crystalline form. The *calcium-salt*, $C^{10}H^{18}Ca''O^6$, crystallises by slow evaporation of aqueous solution in colourless, prismatic crystals, united into stellate groups. Alcol dissolves it less readily than water, and deposits it in wart-shaped masses. The *silv salt*, $C^3H^9AgO^3$, crystallises from hot water in bunches of needles of a silky lustr treated with iodide of ethyl, it yields diethylic lactate. The *zinc-salt* dries up to gummy mass.

DIETHYLIC LACTATE, *Ethyl-lactate of ethyl*.—$C^7H^{14}O^3 = \left.\begin{matrix} C^2H^5 \\ (C^3H^4O)'' \\ C^2H^5 \end{matrix}\right\} O_2$. (Wurt Ann. Ch. Phys. [3] lix. 169.—Wurtz and Friedel, *ibid.* lxiii. 103.—Butlerow, An Ch. Pharm. cxviii. 328). This substance, which may be regarded as the ether of t acid last described, is produced:—1. By the action of ethylate of sodium on chloropr pionate of ethyl (*éther chlorolactique*, Wurtz).—2. By the action of iodide of ethyl ethyl-lactate of silver.—3. By the action of iodide of ethyl on potassio-lactate ethyl.

Diethylic lactate is a transparent, mobile liquid, of an agreeable ethereal odour. boils at 156·5° under a pressure of 757 mm. Its specific gravity at 0° is 0·920 vapour-density, found, 5·052 (calculated, 5·055).

It is insoluble in water, but soluble in alcohol and ether. By ebullition with alkali it is transformed into alcohol and an ethyl-lactate (*vid. supr.*); treatment with am monia converts it into lactamethane (p. 452); it unites directly with lactide, formi diethylic trilactate.

CHLOROLACTIC ETHER, *Éther chlorolactique*. Syn. with *Chloropropionate of eth* (see PROPIONIC ETHERS).

DILACTATE OF ETHYL. See Dilactic acid (p. 461).

DIETHYLIC TRILACTATE, $C^{13}H^{22}O^7 = \left.\begin{matrix} (C^3H^4O)^3 \\ (C^2H^5)^2 \end{matrix}\right\} O^4$. A thick, colourless liqui boiling about 270°, formed by heating diethylic lactate to 170° for several days wi lactide. Potash decomposes it into alcohol and lactic acid. A substance which a pears to be monethylic trilactate, $C^{11}H^{18}O^7 = \left.\begin{matrix} (C^3H^4O)^3 \\ C^2H^5.H \end{matrix}\right\} O^4$, is obtained as secondary product in the preparation of diethylic trilactate. (Wurtz and Friedel

Lactates of Methyl. METHYL-LACTIC ACID, $C^4H^8O^3 = \left.\begin{matrix} CH^3 \\ H \end{matrix}\right\} (C^3H^4O)'' O$, is the on compound belonging to this class that has hitherto been described. It is obtained heating disodic lactate (p. 459) to 110° or 120° with iodide of methyl. *Methyl-la tate of silver*, $C^4H^7AgO^3$, remains as a brittle, amorphous, gummy mass, when i aqueous solution is evaporated *in vacuo*. *Methyl-lactate of zinc* is very solub in water, and uncrystallisable; it dissolves also in absolute alcohol. (Wislicenu Ann. Ch. Pharm. cxxv. 53. G. C. F.

LACTIDE. (True) *Lactic anhydride*. $C^3H^4O^2 = C^3H^4O.O$. (J. Gay-Luss and Pelouze, Ann. Ch. Pharm. vii. 43; Pelouze, *ibid.* liii. 116; Engelhard *ibid.* lxx. 243; Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 101.)—Produced the dry distillation of lactic acid. To prepare it, the product obtained by slowly di tilling lactic acid is evaporated at 100°, and the residue washed with cold alcohol, a crystallised from boiling alcohol. Lactide crystallises in rhomboidal plates of dazzli whiteness. It is inodorous; melts at 107°, and begins to boil at 250°, giving off whit irritating vapours, which sublime without alteration, and condense in crystals on co bodies. It is only slightly soluble in hot water, but is gradually converted into lact acid by ebullition with water, and quickly by the action of bases.

Ammonia converts it into lactamide (p. 453); ethylamine, into lactethylami (p. 453). It unites with diethylic lactate, forming diethylic trilactate (*vid. supr.*). G. C. F.

LACTIDIC ACID. Laurent's name for DILACTIC ACID (p. 461).

LACTIN and **LACTOSE.** Syn. with SUGAR OF MILK.

LACTONE, $C^3H^4O^2$.—A liquid possessing an aromatic smell, and boiling at abo 92°, produced, together with lactide, by the dry distillation of lactic acid. (Pelouz Ann. Ch. Phys. [3] xiii. 262.)

LACTUCA SATIVA. The common lettuce. This plant yields, according T. Richardson (Jahresber. 1847–48, No. 134, Table to p. 1074), 0·87 per cent. as containing:

K^2O	Na^2O	CaO	MgO	SO^3	SiO^2	P^2O^5	Ferric phosphate	NaCl	
46·01	5·29	6·05	2·17	3·89	20·23	8·52	trace	7·82	= 99·98

LACTUCARIUM. A brownish viscid substance obtained by evaporating t

Digitized by Google

juice which exudes, by incision, from the leaves and stems of certain species of *Lactuca*, especially *Lactuca virosa*. It has a peculiar odour resembling that of opium, and acts as a narcotic. German lactucarium contains, according to Ludwig (Arch. Pharm. [2], 7, 129; Jahresber. 1847–8, p. 824), from 44·4 to 53·5 per cent. lactucone; a soft resin; about 4 per cent. of an easy fusible waxy body; lactucin, the chief active principle of the substance; lactucic acid; about 1 per cent. of oxalic acid; a non-volatile not bitter acid, which reduces oxide of silver; and a volatile acid smelling like valerianic acid, both in small quantity only; about 7 per cent. of albumin; at least 2 per cent. mannite; a small quantity of a neutral, not bitter, unfermentable substance, crystallising in rhombic pyramids; and from 3 to 6 per cent. ash, containing potash, soda, manganic oxide, ferric oxide, and a small quantity of lime.

LACTUCERIN. A substance, insoluble in water, contained in lactucarium, probably identical with lactucone.

LACTUCIC ACID. This substance is obtained by triturating lactucarium with an equal weight of dilute sulphuric acid, adding 5 pts. of alcohol of 84 per cent., filtering, shaking up the filtrate with slaked lime, decolorising with animal charcoal, evaporating, heating the residue to boiling with a large quantity of water, and evaporating the aqueous solution, after decolorising it with animal charcoal. A mixture of lactucic acid and lactucin then remains, and on dissolving this in boiling water, the lactucin crystallises out on cooling, and the remaining liquid yields, by evaporation, impure lactucic acid.

Lactucic acid thus obtained is a light yellow mass, amorphous at first, but becoming crystalline after a while; its colourless aqueous solution is coloured wine-red by alkalis, and when boiled with cupric sulphate and excess of soda, reduces the cupric to cuprous oxide. (Ludwig, Jahresber. 1847–48, p. 824.) According to Walz (N. Jahrb. Pharm. xv. 118), it is $C^{36}H^{36}O^{19}$.

LACTUCIN. A substance contained in lactucarium, and supposed to be its active principle. It is obtained by treating the extract with alcohol containing 2 per cent. of strong vinegar, diluting the solution with water, precipitating with basic acetate of lead, removing the excess of lead from the filtrate by sulphydric acid, evaporating at a gentle heat, digesting the residue in ether, and leaving the ethereal solution to evaporate. Ludwig and Kromayer (Arch. Pharm. [2] cxi. 1) prepare it by macerating lactucarium in 1½ pt. hot water for four days, then pressing the mass, again treating it with a little cold water, boiling it five times with fresh portions of alcohol (which leaves lactucone undissolved), and evaporating the extracts to half the bulk of the material used. The product is then precipitated with basic acetate of lead, and recrystallised from alcohol as above.

Lactucin is yellowish, fusible, bitter, soluble in 80 parts of cold water, moderately soluble in alcohol and in acetic acid, less soluble in ether, which deposits it by evaporation in the crystalline state. According to Kromayer (Arch. Pharm. [2] cv. 3), it crystallises in nacreous scales or rhombic tables, probably containing $C^{28}H^{26}O^{7}$ or $C^{28}H^{28}O^{8}$. According to Walz (N. Jahrb. Pharm. xv. 118), it is $C^{36}H^{36}O^{12}$. Nitric acid, of specific gravity 1·48, converts it into a resinous body quite devoid of taste. Strong sulphuric acid turns lactucin brown. Lactucin heated with potash gives off ammoniacal products (?). Its solutions are not precipitated by any reagent. (Buchner, Rep. Pharm. xliii. 1, Gm. xvi. 276.)

LACTUCONE. $C^{40}H^{60}O^{3}$ (?).—A crystalline substance extracted from lactucarium by boiling alcohol. It forms mammillated crystals, which, after purification by recrystallisation and treatment with animal charcoal, are colourless, insipid, melt between 150° and 160°, are insoluble in water, but dissolve very easily in alcohol, ether, and oils, both fixed and volatile. It yields acetic acid in large quantity by distillation. It may, however, be partly volatilised without decomposition in a stream of carbonic acid gas. It yields by analysis 80·56—81·25 per cent. carbon, and 10·91—11·33 hydrogen, numbers which agree nearly with the formula $C^{40}H^{64}O^{3}$. It is an indifferent substance, and is not affected by potash or by chlorine. Its alcoholic solution does not precipitate metallic salts dissolved in alcohol. (Lenoir, Ann. Ch. Pharm. lix. 83.)

LACTUCOPICRIN. An uncrystallisable substance, which remains in the mother-liquors of the preparation of lactucin by Ludwig and Kromayer's process (*vid. sup.*), after the greater part of that substance has been precipitated by basic acetate of lead. When freed from admixed lactucin and lactucone by ether, it forms a brown, amorphous, very bitter mass, having a faint acid reaction, soluble in water and alcohol. It contains 52·6 per cent. carbon, 6·8 hydrogen, and 36·6 oxygen, agreeing nearly with the formula $C^{28}H^{32}O^{10\cdot4}$, and is therefore produced from lactucin by assumption of water and oxygen. (Kromayer, *Die Bitterstoffe*, Erlangen, 1861, p. 79.)

LACTYL, CHLORIDE OF. *Chloride of chloropropionyl.* $C^3H^4OCl^2 = C^3H^4ClO.C$ (Wurtz, Ann. Ch. Phys. [3] lix. 163.—Ulrich, Chem. Soc. Qu. J. xii. 23.)—Obtaine together with oxychloride of phosphorus, by gently heating a mixture of well-dri lactate of calcium with twice its weight of pentachloride of phosphorus. It is difficu to separate the whole of the oxychloride of phosphorus, but the chloride of lactyl m be obtained nearly pure by distilling the liquid, which passes over during the reactio in small quantities at a time, and collecting separately the portion which distils abo 140°. Chloride of lactyl is also formed by the direct combination of ethylene a oxychloride of carbon. (Lippmann.)

When freshly prepared, chloride of lactyl is a colourless liquid, but it soon becom dark coloured, giving off hydrochloric acid. Its boiling point seems to be above 140 but it is partially decomposed when distilled, the thermometer rising to 180° or 190°

It sinks to the bottom of *water* and gradually dissolves, forming hydrochloric a chloropropionic acids (PROPIONIC ACID, DERIVATIVES OF) (Ulrich). With absolu *alcohol*, it reacts very energetically, forming hydrochloric acid, chloride of ethyl, a chloropropionate of ethyl. (Wurtz's *ether chlorolactique.*) G. C. F.

LAGONITE. A ferric borate, $Fe^4O^3.B^2O^3.3H^2O$, occurring as an incrustation the Tuscan lagoons. (Bechi, Sill. Am. J. [2] xvii. 129.)

LAKE. This term is used to denote a species of pigment formed by precipitati colouring matters with some earth or metallic oxide. The principal red lakes are t *Carmine*, *Florence*, and *Madder lakes.*

For the preparation of carmine-lake, four ounces of finely pulverised cochine are poured into 4 or 6 quarts of rain or distilled water (which has been previous boiled in a pewter kettle), and boiled with it for six minutes longer (it is sometim recommended to add, during the boiling, two drachms of pulverised cream of tarta Eight scruples of Roman alum in powder are then added, and the whole is kept up the fire for one minute longer. As soon as the coarse powder has subsided, and t decoction has become clear, the latter is carefully decanted into large cylindrical vesse covered over and kept undisturbed, till a fine powder settles to the bottom. From t decanted liquor, which is still much coloured, the rest of the colouring matter may separated by means of tin-solution: it then yields a carmine-lake but little inferior the other.

For the preparation of Florentine lake, the sediment of cochineal remaining the kettle after the preparation just described may be boiled with the requisite quanti of water, the red liquor which remains after the preparation of the carmine likewi mixed with it, and the whole precipitated with the solution of tin. The red precip tate must be frequently washed with water. Exclusively of this, two ounces of fre cochineal, and one of crystals of tartar, are to be boiled with a sufficient quantity water, poured off clear, and precipitated with the solution of tin, and the precipita washed. At the same time, two pounds of alum are also to be dissolved in water, pr cipitated by caustic potash, and the white earth repeatedly washed with boiling wat Finally, both precipitates are to be mixed together in the liquid state, put upon a filt and dried. For the preparation of a cheaper sort, one pound of Brazil wood may employed in the preceding manner, instead of cochineal.

For the following process for making a *lake from madder*, the Society of Arts vot their gold medal to Sir H. C. Englefield. Enclose two ounces troy of the finest Dut crop madder in a bag of fine and strong calico, large enough to hold three or fo times as much. Put it into a large marble or porcelain mortar, and pour on it a pi of clear soft water, cold. Press the bag in every direction, and pound and rub it abo with a pestle, as much as can be done without tearing it, and when the water is load with colour, pour it off. Repeat this process till the water comes off but slight tinged, for which about five pints will be sufficient. Heat all the liquor in an earth or silver vessel, till it is near boiling, and then pour it into a large basin, into which troy ounce of alum dissolved in a pint of boiling soft water has been previously p Stir the mixture together, and while stirring, pour in gently about an ounce and h of a saturated solution of carbonate of potassium. Let it stand till cold to settle; po off the clear yellow liquor; add to the precipitate a quart of boiling soft water, stirri it well; and when cold, separate by filtration the lake, which should weigh half ounce. If less alum be employed, the colour will be somewhat deeper; with less th three-fourths of an ounce, the whole of the colouring matter will not unite with t alumina. Fresh madder root is equal, if not superior, to the dry.

Almost all vegetable colouring matters may be precipitated into lakes, more or le beautiful, by means of alum or oxide of tin. U.

Yellow lakes are prepared chiefly with decoctions of the berries of vario species of *Rhamnus*, also of fustic, weld, quercitron, &c.; the decoctions, mixed wi carbonate of potassium in greater or smaller quantity as the colour is to be lighter darker, being poured into a hot solution of alum quite free from iron. The colo

carbonate of lanthanum (and didymium) (La; Di)″
ate of cerium. (See CARBONATES, i. 785.)

Digitized by Google

LANTHANUM. *Atomic weight*, 92·8; *Symbol*, La. This metal appears to constantly associated with cerium and didymium. Mosander showed in 18 (Pogg. Ann. xlvi. 648; xlvii. 207) that the red-brown oxide obtained from cerite the manner described under Cerium (i. 831), and originally regarded as the oxi of a single metal, contained the oxide of another metal which he called lanthanu (from λανθάνειν, because it had previously been concealed in the oxide of cerium); a subsequently, in 1841 (Pogg. Ann. lvi. 504), he discovered that this supposed oxi of a single metal, lanthanum, was really a mixture of the oxides of two disti metals, for one of which the name lanthanum was retained, while the other was call didymium (δίδυμοι, twins).

The separation of lanthanum and didymium from cerium may be effected by either the methods described under cerium (i. 831, 832). The second and third are easier a more expeditious than the first. If the solution obtained by treating the crude re brown oxide with dilute nitric acid be evaporated to dryness, and the residue treat with nitric acid diluted with at least 200 pts. of water, a solution will be obtained qui free from cerium (Marignac). Boiling the red-brown oxide with chloride of amm nium also yields a solution of lanthanum and didymium free from cerium. In bo cases, however, it is best to test a portion of the solution for cerium by precipitati with excess of caustic potash, and passing chlorine through the solution. The presen of cerium, even in a very small quantity, will be indicated by the formation of a yell precipitate, after the liquid, supersaturated with chlorine, has been left in a close ves for several hours.

Holzmann, (J. pr. Chem. lxxv. 321; Rép. Chim. pure, i. 241), prepares pure la thanum-salts from the liquid which remains after the precipitation of basic ce sulphate in Bunsen's process for the separation of cerium (i. 832). This liquid, whi contains both lanthanum and didymium, is evaporated (during which process a lar additi nal quantity of cerium separates as basic sulphate) and heated till the great part of the free acid is expelled. The sulphates of lanthanum and didymium, whi then separate out, are dissolved in water containing a little nitric acid, and the solutic together with the mother-liquor, is precipitated with oxalic acid; the precipita mixed with an equal weight of *magnesia alba*, is heated for some time to low re ness; the resulting dark brown oxide is digested with small quantities of dilute nitr acid, which dissolves scarcely anything but the oxides of lanthanum, didymium a magnesium; and the filtrate is boiled for some time with magnesia to separate the la traces of cerium. The liquid is then again precipitated with oxalic acid; the dried a ignited precipitate dissolved in dilute nitric acid; the solution precipitated by sulpha of potassium; the precipitated lanthano- and didymio-potassic sulphates digested wi dilute carbonate of sodium, and the resulting carbonates dissolved in dilute sulphuric aci

A solution free from cerium having been obtained, the separation of the lanthanu and didymium is effected by the different solubilities of their sulphates. To conve them into sulphates, if not already in that form, the solution is treated with excess a caustic alkali, and the washed precipitate dissolved in dilute sulphuric acid. T mode of proceeding varies according as the lanthanum or the didymium is in excess.

1. When the lanthanum is in excess, in which case the solution has but a fai amethyst tinge, the liquid is evaporated to dryness, and the residue heated in a platinu dish to a temperature just below redness, to drive off the excess of acid, and render t sulphates perfectly anhydrous. The residue is then dissolved in rather less than s times its weight of water, at about 2° or 3° C. (36° F.), the salt being reduced powder and added in successive small portions, and the vessel containing the liqu being immersed in ice-cold water. Without these precautions, the temperature of t liquid may be raised several degrees, in consequence of the heat evolved by the comb nation of the anhydrous sulphates with water; and, in that case, crystallisation w commence, and rapidly extend through the whole mass of liquid, as these sulphates a much less soluble in warm than in cold water; but if the liquid be properly cooled, t whole dissolves completely. The solution is next to be heated in the water-bath about 40° C. (104° F.); the sulphate of lanthanum then crystallises out, accompani by only a small quantity of sulphate of didymium. To purify it completely, it is aga rendered anhydrous, re-dissolved in ice-cold water., &c., and the entire process repeat ten or twelve times. The test of purity is perfect whiteness, the smallest quantity didymium imparting an amethyst tinge (Mosander). This process succeeds be when a considerable quantity of the mixed sulphates is operated on.

2. When the didymium-salt is in excess, in which case the liquid has a decided ros colour, separation may be effected by leaving the solution containing excess of acid, a warm place for a day or two. The sulphate of didymium then separates in lar rhombohedral crystals modified with numerous secondary faces; and, at the same tim slender, needle-shaped, violet-coloured crystals are formed, containing the two sulphat mixed. The rhombohedral crystals, which are nearly free from lanthanum, a

Digitized by Google

removed, and the needles, together with the mother-liquid, treated as in the first method, to obtain sulphate of lanthanum. (Mosander.)

In both cases, the separation may be greatly facilitated by first dissolving the mixed oxides of the two metals in a large excess of nitric acid, and precipitating in successive portions by oxalic acid; the first precipitates thus formed have a much deeper rose-colour, and are much richer in didymium than the latter. The separation thus effected is very imperfect in itself, but it greatly facilitates the subsequent separation of the sulphates, which is much more rapid when one of the sulphates is in great excess with regard to the other. (Marignac.)

Metallic lanthanum is obtained by decomposing the anhydrous chloride with sodium, and dissolving out the chloride of sodium with alcohol of specific gravity 0·833. It is a dark, lead-grey powder, soft to the touch, and adhering when pressed.

Lanthanum appears to form only one series of compounds, in which it is diatomic. *e.g.* the *chloride* $LaCl^2$; the *protoxide* LaO.

LANTHANUM, CHLORIDE OF, $LaCl^2$, is obtained in the anhydrous state by igniting the oxide in a current of hydrochloric acid gas (Mosander), or by dissolving the oxide in hydrochloric acid, evaporating the solution, mixed with sal-ammoniac, to dryness, and heating the residue till the sal-ammoniac is expelled. It then remains as a radio-crystalline mass, which deliquesces in moist air, and dissolves easily in alcohol. (R. Hermann, J. pr. Chem. lxxxii. 385.)

A *hydrated chloride*, $LaCl^2.4H^2O$, is obtained as a radio-crystalline mass, by evaporating a solution of the oxide to a syrup, and leaving it over oil of vitriol. When heated in moist air, it gives off water and hydrochloric acid, leaving a mixture of chloride of lanthanum and an oxychloride containing $3LaO.LaCl^2$.

Chloromercurate of Lanthanum, $LaCl^2.3HgCl^2.8H^2O$, is obtained by evaporating a solution of the component chlorides, in colourless cubes, easily soluble in water, but not deliquescent. (Marignac, Ann. Min. [5] xv. 272.)

LANTHANUM, DETECTION and ESTIMATION OF. 1. *Reactions.* Pure lanthanum-compounds fused with borax before the blowpipe, form a perfectly colourless bead; the slightest tinge of amethyst is an indication of the presence of didymium.

Lanthanum-salts in solution are colourless, and have an astringent taste. With caustic *potash* or *soda*, they yield a white bulky gelatinous precipitate of the hydrated oxide, which is insoluble in excess of the alkali, but dissolves completely in chlorine-water, without forming any yellow deposit. *Ammonia* throws down a basic salt. *Oxalic acid* or *oxalate of ammonium* forms a white flocculent precipitate, which does not become crystalline. In other respects the solutions resemble those of cerous salts (i. 833), especially in forming with sulphate of potassium a white crystalline precipitate quite insoluble in excess of the reagent.

2. *Estimation and Separation.*—Lanthanum is best precipitated from its solutions by oxalate of ammonium. The precipitated oxalate, ignited in a covered platinum crucible, is converted into the anhydrous oxide, La^2O, containing 85·4 per cent. of the metal.

The methods of separating lanthanum from most other metals are the same as those adopted for cerium and didymium. The separation of lanthanum from cerium itself may be effected by precipitation with an alkaline hypochlorite, or by boiling the mixed oxides in a solution of sal-ammoniac (i. 832). No method of separating lanthanum from didymium, sufficiently exact for quantitative analysis, has yet been discovered.

3. *Atomic Weight of Lanthanum.*—Mosander, by the analysis of sulphate of lanthanum, estimated the atomic weight of the metal (diatomic) at 92·8. Marignac (Ann. Ch. Phys. [3] xxvii. 209), by a similar method, obtained a somewhat higher number, viz. 94·08. Holzmann (J. pr. Chem. lxxv. 321), from the mean of his analyses of the sulphate and of the iodate, obtained the number 92·8; and R. Hermann (*ibid.* lxxxii. 385), from his analyses of the carbonate, sulphate, and chloride, obtained 92·88. Mosander's determination may, therefore, be regarded as fully confirmed.

LANTHANUM, FLUORIDE OF. Sulphate of lanthanum forms, with fluoride of sodium, a white flocculent precipitate, sparingly soluble in hydrochloric acid. (Hermann.)

LANTHANUM, OXIDES OF. Lanthanum forms two oxides, viz. a *protoxide*, LaO, and a *peroxide*, the composition of which has not perhaps been exactly ascertained.

The protoxide is obtained by igniting the hydrate, carbonate, or oxalate, first in contact with the air, afterwards in contact with the reducing gases of the flame. It then forms white lumps having the same texture as the peroxide, and a specific gravity of 5·94. When exposed to the air, it takes up water and carbonic acid, and in contact

Digitized by Google

with water is converted into the hydrate, LaH^2O^2, which is a soft white powder resembling slaked lime. By precipitating a salt of lanthanum with potash or soda, the hydrate is obtained as a bulky, translucent precipitate, which rapidly absorbs carbonic acid. Both the hydrate and the anhydrous protoxide dissolve easily in acids, without evolution of gas.

The peroxide, said to have the composition $La^{64}O^{63}$ or 64LaO.O, is obtained by igniting the carbonate, oxalate, or nitrate, in contact with the air. It is a light brown or brownish-grey substance, which dissolves in sulphuric, nitric, or acetic acid, with evolution of oxygen, and in hydrochloric acid with evolution of chlorine.

LANTHANUM, OXYCHLORIDE OF, $La^4Cl^2O^3 = LaCl^2.3LaO$, remains on heating the hydrated chloride (p. 469), and after washing with water, forms a white powder, insoluble in water, but dissolving slowly in hydrochloric or nitric abid.

LANTHANUM, OXYGEN-SALTS OF. The solutions obtained by dissolving either of the oxides of lanthanum in acids, are colourless and have an astringent taste. Most salts of lanthanum are soluble in water; but the carbonate, borate, and phosphate are insoluble. Lanthanum has a great tendency to form basic salts, by precipitation with ammonia for example. Many of these salts, the basic nitrate and chloride (oxychloride) for instance, run through the filter as milky liquids during washing. If the precipitate be boiled, the whole runs immediately through the filter; but if it be left in the moist state for a few days, it is converted into a neutral salt, which dissolves in water, while carbonate of lanthanum remains on the filter. Sulphate of lanthanum resembles the corresponding salts of cerium and didymium, in forming with sulphate of potassium a crystalline double salt, sparingly soluble in pure water, and quite insoluble in water saturated with sulphate of potassium.

LANTHANUM, SULPHIDE OF, LaS, is obtained by igniting the metal in vapour of sulphide of carbon, as a yellow powder, which is decomposed by water, with evolution of sulphydric acid, and formation of the white hydrate of lanthanum. The sulphide may also be obtained by igniting the oxide in vapour of sulphide of carbon, or by fusing it with sulphide of sodium; but it is then of a fiery yellow colour, and when examined by the microscope, is seen to be made up of fine crystals. (Mosander.)

LAPATHIN. The name given by Buchner and Herberger (Rep. Pharm. xxxviii. 337), to a substance which they obtained in a very impure state from the root of *Rumex obtusifolius* (the officinal *Radix lapathi acuti*): it has since been shown to be identical with chrysophanic acid (i. 958).

LAPIS LAZULI. *Ultramarine. Lasurstein.*—A silicate of sodium, calcium, and aluminium mixed with a sulphur-compound of sodium. It occurs sometimes in rhombic dodecahedrons, with imperfect dodecahedral cleavage, but more commonly massive and compact. Hardness = 5·5. Specific gravity = 2·38 to 2·45. Lustre vitreous. Colour rich Berlin or azure blue. Translucent to opaque. Fracture uneven. Before the blowpipe it fuses to a white glass, and if calcined and reduced to powder, loses its colour, and gelatinises in hydrochloric acid. With borax, it effervesces and forms a colourless glass.

Analyses:—1. From the East: *a.* Klaproth (*Beitrage*, i. 189); *b.* L. Gmelin (Schw. J. xiv. 329); *c.* Varrentrapp (Pogg. Ann. xlix. 515); *d.* Köhler (*Rammelsberg's Mineralchemie*, p. 710); *e.* Schultz (*ibid.*).—2. From Vesuvius: L. Gmelin (*loc. cit.*).—3. From the Andes: *a.* Field (Chem. Soc. Qu. J. iv. 331); *b.* Schultz (*loc. cit.*):—

These analyses show that lapis lazuli is not a mineral of definite constitution, but a mixture, a result which is corroborated by its appearance and physical structure. It

Digitized by Google

is, therefore, useless to attempt the calculation of a formula from the analyses. On examining thin slices of the mineral under the microscope, the blue colouring matter is seen to be distributed amidst a white ground. The composition of artificial ultramarine renders it probable that the colouring matter of the natural mineral is either a polysulphide of sodium, or a compound of the protosulphide with a polythionate of sodium.

Lapis lazuli is usually found in granite or in crystalline lime-stones. It is brought chiefly from China, Siberia, and Bucharia; the specimens often contain scales of mica and pyrites. On the banks of the Indus, it occurs disseminated in a greyish limestone.

The richly coloured varieties are highly esteemed for making costly vases and ornamental furniture; it is also employed in the manufacture of mosaics, and when powdered constitutes the rich and durable pigment called ultramarine (*q.v.*)

LAPIS OLLARIS or *Potstone* is a coarse granular dark-coloured variety of steatite.

LARCH. See LARIX.

LARDERELLITE. A borate of ammonium occurring at the lagoons of Tuscany, as a white efflorescence composed of microscopic crystals. It contains, according to Bechi (Sill. Am. J. [2] xvii. 130), 68·55 per cent. boric anhydride, 11·73 oxide of ammonium, and 18·32 water, agreeing nearly with the formula $(NH^4)^2O.4B^2O^3.4H^2O$. It is soluble in water, and the hot solution yields another salt, composed of $(NH^4)^2O.6B^2O^3.9H^2O$.

LARDITE. A variety of talc (*q.v.*); also syn. with AGALMATOLITE.

LARIX EUROPÆA or *Pinus Larix*. The Larch tree. The young branches of this tree exude a kind of manna, from which Berthelot has obtained a fermentable sugar called melezitose (*q.v.*) The bark contains a peculiar acid, to be described in the next article.

LARIXINIC ACID. $C^{16}H^{16}O^8$. (Stenhouse, Phil. Trans., 1863, p. 53; Proc. Roy. Soc. xi. 405.)—A volatile crystallisable acid contained in the bark of the larch-tree, most abundantly in that of the smaller branches of trees from 20 to 30 years old. It is obtained by exhausting the bark with water at 80°, evaporating the extract to a syrup and distilling in vessels of glass, porcelain, or silver. The acid which passes over crystallises, partly on the inner surface of the receiver, but the greater part is obtained in the crystalline form on evaporating the distillate. The brown-yellow crystals thus obtained are purified by recrystallisation and sublimation.

Sublimed larixinic acid forms crystals resembling those of benzoic acid, often an inch long, and having a brilliant silvery lustre; they are monoclinic and usually occur in twins. The crystals deposited from water are also monoclinic. The acid sublimes at 93°, melts at 153°, often volatilises with vapour of water, has a slightly bitter astringent taste, and smells like camphor or naphthalene. The crystals catch fire readily, and burn with a bright flame, leaving no residue. The acid reddens litmus slightly. dissolves in 87·9 pts. *water* at 60°, more easily in boiling water and in *alcohol*, sparingly in *ether*. *Nitric acid* converts it into oxalic acid. When treated with *hydrochloric acid* and *chlorate of potassium* it does not yield chloranil.

The aqueous solution of larixinic acid is precipitated by *baryta-water*, forming an easily decomposible precipitate which contains 34·9 per cent. baryta. The acid is not precipitated by *lime-water* or *sugar-lime*, or by *lead-*, or *silver-salts*; neither does it reduce the metal from the latter on boiling. *Ferric salts* produce, even in dilute solution of larixinic acid, a characteristic purple-red colour.

Larixinate of potassium forms flat red-brown crystals which become darker on recrystallisation, and are decomposed, even by carbonic acid.

Larixinic acid is not found in the bark of *Abies excelsior*, or *Pinus sylvestris*.

LASIONITE. Syn. with WAVELLITE.

LASURITE. Blue carbonate of copper (i. 783).

LASYLIC ACID. $C^7H^8O^2$. An acid whose phenyl-ether, $C^{13}H^{12}O^2 = C^7H^7(C^6H^5)O^2$, is produced, together with hydrochloric acid. by the action of oxychloride of phosphorus in excess on salicylate of sodium. When the temperature rises high, a viscid liquid passes over, which, on standing, deposits tabular crystals of the phenyl-ether, leaving a mother-liquor which smells of hydrate of phenyl. (Kolbe and Lautemann, Ann. Ch. Pharm. cxv. 157.)

LATERITE (from *later*, a brick) is a name applied by Indian geologists to a formation common in Ceylon and India, and consisting of reddish clay, more or less hardened, and enclosing nodules of quartz: the Cingalese call it cabook. True laterite is a hard, dense, almost jasper-like, reddish or brick-red rock, consisting of hardened

Digitized by Google

clay enclosing quartz-crystals. A second variety, which is most common in Ceylon, is softer, may be cut with the knife, but hardens on exposure to the air. A third kind is sedimentary or breccia-like, consisting of quartz-nodules loosely embedded in clay, and has been produced by disintegration of true laterite, which appears to be itself a product of the decomposition of granite or gneiss containing hornblende. (Jahresber. 1853, p. 892.)

LATEX. A juice which circulates through plants by means of a set of vessels called the laticiferous tissue or cinenchyma, and coagulates into a gelatinous substance called cambium, which precedes the formation of cells. The descending juice is, according to Frémy, a mixture of several liquids, some of which contain vegetable secretions, while others serve for the development of vegetable organs. In those parts of the vegetable organism which are in process of development, there exists a kind of juice called by Frémy, the *albuminiferous latex*, which closely resembles the young organs in chemical composition, and forms the material for the production of the cambium. Under favourable circumstances, this juice may be obtained tolerably pure by making a slight incision into the growing tissues just below the epidermis. This juice—which is obtained with essentially the same properties from the leaf-stalks of *Colocasia odora*, and the banana tree, the stems of *Stephanotis* and *Tanghinia*, the roots of the arum, and the parenchyma of the gourd—coagulates completely when heated, or on addition of a trace of nitric or tannic acid. It usually exhibits the alkalinity of serum or of egg-albumin; leaves, when dried up, a residue consisting almost wholly of albumin (in fact it is as rich in albumin as blood-serum or milk), and yields ash consisting mainly of alkaline chlorides and carbonates. (Frémy, Compt. rend. li. 647.)

LATHYRUS ANGUSTIFOLIUS. In the seed of this plant, Reinsch found an uncrystallisable bitter substance, vegetable fibre, starch, legumin, vegetable albumin, gum, salts, a fixed oil, a resinous and a waxy substance.

LATROBITE. Syn. with ANORTHITE.

LAUMONTITE. *Laumonite, Lomonite, Efflorescing zeolite.*—A hydrated silicate of calcium and aluminium, occurring in monoclinic crystals, in which the principal axis, orthodiagonal and clinodiagonal are to one another as 0·516 : 1 : 0·8727, and the inclined axes make an angle of 68° 40′. Angle $\infty P : \infty P = 86° 16'$; $oP . (P\infty) = 151° 9'$. Observed planes $oP . \infty P . (\infty P\infty) . +P . -P . -2P\infty$. Cleavage perfect parallel to $\infty P\infty$, also to ∞P. The mineral occurs also in columnar, radiating, or divergent forms. Hardness = 3·5 to 4. Specific gravity = 2·29 to 2·36. Lustre vitreous, inclining to pearly on the cleavage-faces. Colour white, passing into yellow or grey, sometimes red. Streak uncoloured. Transparent or translucent; becomes opaque, and usually pulverulent on exposure. Fracture scarcely observable, uneven. Not very brittle. Before the blowpipe it intumesces and melts to a frothy mass; forms a transparent bead with borax. It gelatinises with nitric or hydrochloric acid, but is not affected by sulphuric acid.

Analyses: *a.* From Phipsburg, State of Maine (Dufrénoy, Ann. Min. [3] viii. 303,—*b.* From Courmayeur, Savoy (Dufrénoy, *ibid.*).—*c.* From Skye (Connel, Edinb J. of Sc. 1829, p. 252).—*d.* From Huelgoet, Bretagne (Malaguti and Durocher, Ann. Min. [4] ix. 325).—*e.* Red variety from Upsala (Berlin, Pogg. Ann. lxxviii. 415).—*f.* From Port George, Nova Scotia (How, Sill. Am. J. [2] xxvi. 30).

	SiO^2	Al^2O^3	Fe^2O^3	CaO	H^2O	
a.	51·98	21·12	. .	11·71	15·05	= 99·86
b.	50·38	21·43	. .	11·14	16·15	= 99·10
c.	52·04	21·14	. .	10·62	14·92	= 98·72
d.	52·47	22·56	. .	9·41	15·56	= 100
e.	51·61	19·06	2·96	12·53	14·02	= 100·18
f.	50·43	21·64	. .	12·07	15·26	= 100·40

These analyses lead to the formula $CaO.Al^2O^3.4SiO^2 + 4H^2O$ (requiring 51·63 SiO^2, 21·51 Al^2O^3, 11·78 CaO, 15·08 H^2O), or $Ca''(Al^2)^{vi}Si^4O^{12}.4H^2O$, which is reducible to that of a hydrated metasilicate, $R^2SiO^3.H^2O$.

Laumontite occurs in the cavities of amygdaloïd, also in porphyry and syenite, and occasionally with calcspar, in veins traversing clay-slate. Its principal localities are in the Faroe Islands, at Diako in Greenland, at Eule in Bohemia, in clay-slate on the St. Gothard, and in large masses in the Fassa valley; at Hartfield Moss in Renfrewshire, accompanying analcime; in the amygdaloïd rocks of the Kilpatrick Hills near Glasgow; and in several trap-rocks of the Hebrides and the north of Ireland. Fine specimens are found at Peter's Point, Nova Scotia; it is also abundant in many places in the copper-veins of Lake Superior, and in several other localities of North America.

Digitized by Google

Laumontite is remarkable for the facility with which it gives up its combined water, in consequence of which it is often found opaque and friable. This change may be prevented in cabinet specimens by dipping them in a thin solution of gum-arabic. According to Malaguti and Durocher, it loses 2·26 per cent. water when kept for a month in a vacuum, and 3·65 in the exsiccator over sulphuric acid. In damp air it does not effloresce; and the effloresced mineral, when exposed to such an atmosphere, recovers the water which it has lost.

Sometimes the alteration of laumontite by natural processes goes a step further, and carbonate of calcium is formed. A laumontite from Oberscheld, near Dillenburg, thus altered, contains (dried at 100°), according to Wildenstein (Jahresber. 1850, p. 734),

SiO^2	Al^2O^3	Fe^2O^3	CaO	H^2O	CO^2		
39·12	13·43	2·60	25·18	6·22	13·45	=	100

or, deducting carbonate of calcium:

56·33	19·34	3·73	11·64	8·96	. .	=	100

It has therefore been converted into a mixture of laumontite containing only half of the original quantity of water, with carbonate of calcium and a small quantity of free silica.

Laumontite likewise occurs more or less altered to orthoclase (C. Bischof, *Rammelsberg's Mineralchemie*, p. 631; Lewinstein, *ibid.* p. 997; Jahresber. 1860, p. 771).

Caporcianite (i. 741) is perhaps an altered laumontite.—*Schneiderite*, a zeolite from the gabbro of Tuscany, and containing, according to Bechi (Sill. Am. J. [2] xiv. 64), 47·79 per cent. silver, 19·98 alumina, 16·76 lime, 11·04 magnesia, 1·62 alkali, and 3·41 water, is, according to Breithaupt, a decomposed laumontite. Berlin regards *edelforsite* (ii. 361), and similar minerals from Fahlun and Martenberg in Sweden, as decomposed laumontites.

LAURELIC ACID. An acid obtained, according to Grosourdi (Jahresber. 1851, p. 562), from the berries of *Laurus nobilis* (p. 477).

LAURIC ACID. $C^{12}H^{24}O^2 = \left.\begin{matrix} C^{12}H^{23}O \\ H \end{matrix}\right\}O$. *Laurostearic acid. Pichuric acid.*

(Marsson, Ann. Ch. Pharm. xli. 33.—Sthamer, *ibid.* liii. 393.—Görgey, *ibid.* lxvi. 303.—Heintz, Pogg. Ann. xcii. 429 and 583; J. pr. Chem. lxvi. 1.—A. C. Oudemans, Jun., J. pr. Chem. lxxxi. 356.—Gm. xv. 43.)—This acid, belonging to the series $C^nH^{2n}O^2$, occurs in the fat of the bay-tree, *Laurus nobilis* (Marsson); in the fat of pichurim-beans (Sthamer); also in the volatile oil of these beans (A. Müller, J. pr. Chem. lviii. 469); in small quantity, together with many other acids, in spermaceti (Heintz); in croton-oil (Schlippe, Ann. Ch. Pharm. cv. 14); in the fruit of *Cyclicodaphne sebifera* (Gorkom, Tydschrift af Necrl. Indie, lxxxi. 410); in the so-called Dika bread, the fruit of *Mangifera gabonensis*, together with myristic acid, but unaccompanied by any other acids (Oudemans); in the age or axin of the Mexicans, a salve-like fat obtained from *Coccus Axia* (Hoppe, J. pr. Chem. lxxx. 102); and in cocoa-nut oil (Görgey and Oudemans). It may be formed artificially by heating ethal (cetylic alcohol) with potash-lime to 275°—280° (Heintz, Scharling). According to Heintz, it is produced only from mixed (crude) ethal, inasmuch as this substance contains lethal:

$$C^{32}H^{34}O + KHO = C^{12}H^{23}KO^2 + 2H^2.$$

But, according to Scharling, it is obtained from the ethal itself, $C^{16}H^{34}O$, which, according to him, is decomposed by heating with potash-lime, in such a manner as to yield stearic, palmitic, myristic, lauric, and butyric acids. (Scharling, Ann. Ch. Pharm. xcvi. 236; Heintz, Ann. Ch. Pharm. xcvii. 271.)

Preparation.—1. *From Bay-fat.* Laurostearin from commercial oil of bay (p. 476) is saponified with potash-ley; the soap is separated by common salt, and its hot aqueous solution is decomposed with tartaric acid. The lauric acid then rises to the surface in the form of an oil which solidifies on cooling, and is freed from adhering tartaric acid by repeated fusion with water. (Marsson.)

2. *From Pichurim beans.*—Laurostearin from *Fabæ pichurim maj.* is saponified with potash-ley till a clear soap-jelly is formed; common salt is added, and the white, brittle soda-soap thus produced is dissolved in boiling water, and supersaturated at the boiling heat with hydrochloric acid; lauric acid then rises to the surface as a colourless oil, which on cooling solidifies to a white crystalline mass. It is freed from hydrochloric acid by repeated washing with water, and purified by repeated crystallisation from weak alcohol. (Sthamer.)

3. *From Cocoa-nut oil.*—The oil is saponified with weak potash-ley; the soap

Digitized by Google

decomposed by dilute sulphuric acid, and the mixture distilled as long as fatty acids pass over, the water being repeatedly poured back. The distillate neutralised with potash, solidifies on evaporation to a gelatinous soap, which is separated by common salt, repeatedly dissolved in potash and again separated with salt, to free it from the fatty acids which can be thus removed, and again decomposed with dilute sulphuric acid. It is then neutralised with ammonia; the solution precipitated by chloride of barium; the liquid strained off; and the barium-salts which remain repeatedly boiled with water. The resulting solutions, as they run from the funnel, immediately deposit loose flocks of laurate of barium, and the liquid, as it cools down, becomes turbid and deposits pulverulent caprate of barium. (Görgey; see also *Prep.* 5.)

4. *From Spermaceti.*—The saponification of this substance yields, besides ethal, considerable quantities of stearic, palmitic, and myristic acids, and smaller quantities of lauric acid.—The solution of 10 lbs. of purified spermaceti in 30 lbs. alcohol is boiled for some time with 4½ lbs. caustic potash previously dissolved in alcohol; the solution precipitated with aqueous chloride of barium, and strained while hot; the still warm residue pressed as strongly as possible in a warmed press, then well moistened with alcohol and again pressed; the alcohol distilled off from the solutions; the residue freed from the whole of the soluble matter by repeated treatment with ether; and the portion insoluble in ether added to the barium-salts previously obtained. In this manner are obtained, on the one hand, crude ethal; on the other, the barium-salts of the fatty acids of spermaceti.

The barium-salts suspended in water are boiled with very dilute hydrochloric acid, till the supernatant oily layer appears perfectly clear; the fatty acids thus obtained are dissolved in alcohol; the solution is left to cool; and the crystals which separate are pressed, first alone, then several times after being moistened with alcohol; whereby a mixture of palmitic and stearic acids is separated, while a portion of these two acids, and the whole of the myristic and lauric acids, remain in solution.

The whole of the mixed alcoholic solutions are heated; a concentrated aqueous solution of acetate of magnesium is added, so as to precipitate about $\frac{1}{50}$ of the quantity of fatty acids present; the precipitate which forms on cooling is separated by filtration; acetate of magnesium added to the filtrate in about the same quantity as before, and the same treatment repeated (the liberated acetic acid being neutralised towards the end with ammonia), till acetate of magnesium no longer forms any precipitate even in presence of excess of ammonia. In this manner a number of magnesium-salts (19) are obtained, from which stearic, palmitic, and myristic acids may be separated by processes to be hereafter described in connection with these acids.

The alcoholic solution, from which everything precipitable by acetate of magnesium in presence of excess of ammonia has been thus removed, still retains lauric acid, together with myristic and oleic acids. It is precipitated with acetate of lead; the precipitate is washed with dilute alcohol, dried, and freed from a small quantity of oleate of lead, by treatment with ether; and the undissolved portion is decomposed by prolonged and repeated boiling with very dilute hydrochloric acid, whereby a mixture of acids melting at 39·7° is separated. By repeatedly crystallising this mixture from alcohol, as long as the separated acid exhibits a rise of melting point, lauric acid is ultimately obtained, melting at 43·6°, and not capable of further decomposition by partial precipitation with acetate of barium, while myristic acid remains in solution. (Heintz.)

5. From spermaceti or other fats containing lauric acid, provided they are free from oleic acid, or this acid has been removed by the process to be described below.—The fat is saponified with alcoholic potash; the fatty acids are separated from the ethal or the glycerin, as above described, and dissolved in 10 pts. of hot alcohol; the solution is left to cool slowly in a cellar; and the fatty acids which crystallise out are separated by filtration and pressure. The mother-liquor is diluted with an equal quantity of boiling alcohol and supersaturated with ammonia; acetate of magnesium is added in excess to remove a certain portion of the fatty acids; the alcohol distilled off from the filtrate; the remaining salts decomposed by boiling with dilute hydrochloric acid; the separated acids re-dissolved in a quantity of hot alcohol sufficient to retain them in solution after cooling; and a concentrated solution of acetate of barium equal to about $\frac{1}{12}$ of the weight of the fatty acids, is repeatedly added, as long as a precipitate is thereby formed on cooling. The precipitates last obtained, which contain chiefly lauric acid, are separately decomposed by boiling dilute hydrochloric acid, and each portion of acid thereby liberated, whose melting point lies above 43·6 is separately and repeatedly crystallised from dilute alcohol, till its melting point has risen to 43·6. (Heintz.)

Digitized by Google

If the fat contains oleic acid, it is saponified, the fatty acid is separated and mixed with a small quantity of hot alcohol, and the solid portions are removed by submitting the cooled mass to pressure The mother-liquor (together with the alcohol used for washing the separated acids) is precipitated with ammonia and neutral acetate of lead; the washed and dried lead-salts are completely freed from oleate of lead by means of ether; the undissolved portion is decomposed by boiling hydrochloric acid; and the separated fatty acids are treated as above (Heintz). In this manner, pure lauric acid is easily obtained from cocoa-nut oil (which, according to Oudemans, does not contain oleic acid). If the acids dissolved in alcohol be precipitated in small portions with acetate of barium, the first portions contain palmitic and myristic acids; and from the remaining liquid, lauric acid may be obtained by repeated fractional precipitation, or by crystallisation in the cold. (Oudemans.)

Properties.—Lauric acid solidifies after fusion to a scaly crystalline mass, exhibiting a laminated texture on the fractured surface; from alcohol, in white, silky needles, united in tufts, or in prickly glandular scales. It melts to a colourless oil at 43·6° (Heintz), 42°–43° (Marsson, Görgey), 43° (Sthamer), 45° (Müller), 43·3° (Schlippe), 43·5 (Oudemans). The alcoholic solution has a slight acid reaction. Specific gravity 0·883 at 20° (Görgey). When boiled with water it volatilises with the vapour. (Görgey, Oudemans.)

It is insoluble in *water*, but dissolves easily in *alcohol* and in *ether*.

By the distillation of its calcium-salt, lauric acid is resolved into laurostearone and carbonate of calcium. (Overbeck):

$$2C^{12}H^{24}O^2 = C^{23}H^{46}O + CO^2 + H^2O.$$

Laurates. Lauric acid is monobasic, the general formula of its salts being $M'C^{12}H^{23}O^2$, and $M''(C^{12}H^{23}O^2)^2$.

The *barium-salt*, $Ba''(C^{12}H^{23}O^2)^2$, is prepared as above described (p. 474), and crystallises on cooling from a boiling saturated aqueous solution in snow-white flakes. The saturated alcoholic solution becomes filled, on cooling, with delicate crystalline spangles, which, after drying at 100°, resemble caprate of barium (Görgey). It is wetted by alcohol and ether, but not by water (Görgey). Dissolves in 10,864 pts. of water at 17·5°, in 1·982 pts. boiling *water*, in 1,468 pts. cold and 211 pts. hot *alcohol* (Görgey). Decomposes before melting. (Heintz.)

The *calcium-salt* is a white precipitate, obtained by mixing the solutions of laurate of sodium and chloride of calcium.

The *lead-salt*, $Pb''(C^{12}H^{23}O^2)^2$, forms a snow-white, loose, amorphous powder (Heintz); *aminæ*, having a beautiful nacreous lustre (Müller). It melts between 110° and 120°, and solidifies to a dull, amorphous mass (Heintz); melts below 100° to a colourless liquid, which solidifies in the crystalline form on cooling (Müller). It is insoluble in *water*; insoluble in cold, sparingly soluble in boiling *alcohol*. (Müller.)

The *copper-salt*, $Cu''(C^{12}H^{23}O^2)^2$, is obtained by precipitating the hot alcoholic solution of the aqueous sodium-salt with aqueous sulphate of copper.

The *silver-salt*, $AgC^{12}H^{23}O^2$, obtained by precipitating the solution of the sodium-salt in weak alcohol with nitrate of silver, is a white powder, consisting of slender microscopic needles (Heintz). It dissolves easily in ammonia, and crystallises from the hot concentrated solution in very small needles (Marsson). It is scarcely or not at all altered by light, but decomposes before fusion when heated. (Heintz.)

The *sodium-salt*, $NaC^{12}H^{23}O^2$, prepared by nearly saturating a boiling solution of pure carbonate of sodium with lauric acid, evaporating over the water-bath, dissolving the remaining soap in alcohol, and evaporating the filtrate to dryness, forms a white powder, whose alcoholic solution solidifies on cooling to a white opaque jelly. The aqueous solution becomes turbid when largely diluted with water.

LAURIC ETHERS. *Laurate of Ethyl*, $C^{12}H^{23}O^2.C^2H^5$, is prepared by passing hydrochloric acid gas into an alcoholic solution of lauric acid, adding water, which separates the ether, washing first with alkaline, then with pure water, and drying over chloride of calcium. It is a colourless oil, having a fruity odour and sickly taste. Specific gravity 0·86 at 20° (Görgey). Crystallises at 10°. Boils at 269°, when the barometer stands at 750 mm. (Delffs); at 264°, with partial decomposition. (Görgey.)

Vapour-density by experiment 8·4; by calculation (2 vol.) = 7·9.

Laurate of Glyceryl, or *Laurostearin*. $C^{37}H^{70}O^6$ [or rather, perhaps, $C^{37}H^{68}O^5 = \left.\begin{matrix}(C^3H^5)'''\\ H.(C^{12}H^{23}O)^2\end{matrix}\right\}O^3$].—This fatty body is found in the berries of the sweet bay-tree (*Laurus nobilis*) (Marsson); also in cocoa-nut oil (Görgey), and in pichurim beans. (Sthamer.)

Preparation.—1. *From the berries of the Bay-tree.*—These berries are treated with

Digitized by Google

boiling alcohol; the solution is filtered hot; the crystals of impure laurostearin w separate on cooling are melted over the water-bath; the liquid thus obtained is filt to separate a resinous substance which accompanies it; and the remaining lauroste is purified by repeated crystallisation from alcohol. It is thus obtained perfectly p

2. *From Commercial Oil of Bay.*—The oil is exposed to sunshine on porcelain p covered with glass shades, whereupon the green colour soon disappears, and br hard lumps of laurostearin separate from the mass of fat melted by the sun's h these are separated by filtration, dissolved in alcohol, and obtained of a pure whit evaporation or by precipitation with water. (Bolley.)

3. *From Pichurim beans* (*Fabæ pichurim major.*).—The beans are exhausted with alcohol (which extracts volatile oil, pichurim-camphor, resin, a buttery fat, and a br colouring matter); and the exhausted beans are boiled with alcohol of 81 per c and pressed between hot plates. The expressed liquid, as it cools, deposits pale ye laurostearin, only a small quantity of that substance remaining dissolved in the alc It is purified by washing with cold alcohol, pressure, and recrystallisation from et alcohol. (Sthamer.)

Laurostearin forms white needles having a silky lustre, melting at about 44°, s ingly soluble in cold alcohol, moderately soluble in boiling alcohol, very solubl ether. By dry distillation, it yields acrolein. When treated with alkalis, it is reso into glycerin and lauric acid.

Laurostearin gives by analysis 73·19 to 73·53 per cent. carbon, and 11·45 to 1 hydrogen, agreeing nearly with the formula $C^{57}H^{56}O^{4}$ (calc. 73·97 C, 11·41 H, 14·62 O), according to which, laurostearin contains the elements of 2 at. lauric + 1 at. glycerin − 3 at. water:

$$2C^{12}H^{24}O^{2} + C^{3}H^{8}O^{3} - 3H^{2}O = C^{57}H^{56}O^{4}.$$

This, however, does not agree with the constitution of the normal glycerides (ii. 8 Perhaps, therefore, the true formula may be $C^{57}H^{52}O^{5} = 2C^{12}H^{24}O^{2} + C^{3}H^{8}O^{3} - 2H^{2}$ $\left.\begin{matrix}(C^{3}H^{5})''' \\ C^{12}H^{23}O)^{2} \\ H\end{matrix}\right\}O^{3}$.

LAURIN. *Bay-berry Camphor.*—A substance discovered by Bonastre (J. Pha x. 32) in the berries of the bay-tree, and further examined by Marsson (Ann. Pharm. xli. 329) and Delffs (*ibid.* lxxxviii. 354). It is prepared by boiling skinned and pounded berries with alcohol of 85 to 90 per cent., filtering at the boi heat, and leaving the liquid to itself for several days. Laurostearin is then first de sited; and on filtering again and leaving the liquid to evaporate, laurin is deposited crystals contaminated with a viscid oil, from which they may be freed by press between paper and recrystallisation.

Laurin forms crystals belonging to the dimetric system, destitute of taste and sm insoluble in water, very soluble in alcohol, even in the cold—also in ether. The so tions are neutral to test-papers. Laurin does not dissolve in alkalis.

According to the analysis by Delffs, laurin contains 76·5—77·1 per cent. carbon, a 86·92 hydrogen, numbers agreeing approximately with the formula $C^{22}H^{30}O^{2}$.

Laurin cannot be distilled without decomposition. Its alcoholic solution is precipitated by acetate of lead or nitrate of silver.

LAURONE. $C^{23}H^{46}O = C^{12}H^{23}O.C^{11}H^{23}$? *Laurostearone.*—A substance produ by the dry distillation of laurate of calcium. It crystallises from alcohol in shini plates, which melt at 66°. It becomes electric by friction. Gives by analysis 81 and 81·04 per cent. C, and 13·82—14·10 H, agreeing nearly with the preceding form (81·65 C, 13·61 H, and 4·74 O), which is that of the acetone of lauric acid. (Ov beck, Pogg. Ann. lxxxvi. 591.)

LAUROSTEARIN. See Laurate of Glyceryl (p. 475).

LAURUS CAMPHORA, OIL OF. See i. 729.

LAURUS NOBILIS. The *Sweet Bay-tree.*—The fruit of this tree has be analysed by Grosourdi (J. Chim. méd. [3] vii. 257, 321, 385; Jahresber. 1851, p. 56 He finds that, in the fresh berries, the pericarp constitutes nearly a third of the enti weight; the kernels, freed from episperm, make up more than half the weight of t seed; and the episperm amounts to rather more than $\frac{1}{11}$th of the weight of the fre seed.

100 pts. of the dried berries yielded 0·86 silica, 0·12 carbonate of calcium, 0·12 oxid of iron and manganese. 0·53 carbonate of potassium, 0·07 sulphate of potassium, 0·1 chloride potassium: in all, = 1·75 per cent. ash.

The composition of the entire fresh fruit, pericarp and kernel (cotyledons), is give in the following table:—

Digitized by Google

	100·120	100·010	100·729

Laurelic acid was obtained by treating the pericarp with water, precipitating the pectin with alcohol, evaporating the alcoholic liquid, dissolving the residue in water, precipitating the aqueous solution with nitrate of lead, and decomposing the precipitate with sulphydric acid.

Stearolaurin (? identical with laurostearin) is the solid fat which gradually separates at 10° from the warm-pressed oil of the pericarp.—*Phæosin* or *Phæosic acid* is a brown substance extracted by carbonate of sodium from the pericarp, exhausted successively with water, alcohol, and ether.

LAVA. See Volcanic Products.

LAVENDER, OIL OF. Lavender (*Lavandula Spica*, L.) yields a yellowish volatile oil, having a strong but agreeable odour, and an acrid aromatic taste. It reddens litmus, and contains, in variable proportions, a crystalline substance having the composition of common camphor (Dumas). The liquid portion of the oil appears to be mainly composed of two substances, one of which has the composition of oil of turpentine. (Gerhardt, *Traité*, iv. 336.)

LAVENDULAN. An amorphous mineral from Annaberg in Saxony, which appears to be an arsenate of cobalt, mixed with the arsenates of nickel and copper. It has a greasy lustre, inclining to vitreous. Hardness = 2·5 to 3. Specific gravity = 3·014. Colour lavender-blue. Streak paler blue. Translucent. Fracture conchoïdal. Melts easily before the blowpipe, colouring the flame blue, and becoming crystalline on cooling. (Breithaupt, J. pr. Chem. x. 505.)

LAZULITE. *Azurite. Azure-stone. Blue Spar. Voraulite. Klaprothin.*—A hydrated phosphate of aluminium, magnesium, and iron, occurring in monoclinic pyramids, with truncated summits and several secondary faces. The inclined axes make an angle of 88° 15′; and the principal axes, orthodiagonal and clinodiagonal, are to one another as 0·86904 : 1 : 1·0260. Angle $\infty P : \infty P = 91° 30'$; $oP : P\infty = 139° 45'$. Observed faces, $+2P\infty$, $-2P\infty$, $-2P$, oP, $+2P$, $-P$, and others. Twin-crystals also occur with face of composition $\infty P\infty$. Cleavage lateral, indistinct. The mineral also occurs massive.

Hardness = 5 to 6. Specific gravity = 3·057 (Fuchs); 3·067 to 3·121 (Prüfer); 3·122 (Smith and Brush). Lustre vitreous. Colour azure-blue, commonly of a fine deep blue when viewed along one axis, and a pale greenish-blue along another.

When heated in a tube, it gives off water and turns white. Before the blowpipe, it colours the flame faint green, swells up, becomes tumid, but does not melt; gives a fine blue colour with cobalt solution.

Analyses.—*a.* Light blue from Krieglach in Styria: mean of two analyses (Rammelsberg, *Mineralchemie*, p. 340).—*b.* Light blue from near Werfen in Saltzburg (Fuchs, Schw. J. xxiv. 373).—*c.* Dark blue from the Fischbach Alp in Styria: mean of two analyses (Rammelsberg, *loc. cit.*).—*d.* Dark blue from Sinclair County, North Carolina (Smith and Brush, Sill. Am. J. [2] xvi. 365).

	P^2O^5	Al^2O^3	MgO	FeO	CaO	H^2O		
a.	44·16	33·14	12·52	1·77	1·53	6·88	=	100
b.	42·70	36·50	9·54	2·70	. .	6·19	=	97·63
c.	42·58	32·89	9·27	8·11	1·11	6·04	=	100
d.	43·76	31·70	10·01	8·17	. .	5·59	=	99·26

Digitized by Google

From these numbers Rammelsberg deduces the formula, $[3(Mg;Fe)''O.P^2O^5 + 3Al^2O^3.P^2O^5 + 3H^2O$. The darker varieties contain a larger proportion of iron than the lighter varieties.

Lazulite occurs in narrow veins traversing clay-slate, in the torrent beds of Schladming and Rädelgraben, near Werfen in Saltzburg, and the other localities above mentioned; also at Tijuco in Minas Geraes, Brazil. It is abundant at Crowder's Mount, Lincoln County, North Carolina. (Dana, li. 405.)

LEAD. Synonyms: *Blei; Plomb; Plumbum; Saturnum.* Symbol, Pb. Atomic weight, 207.

This metal does not often occur in nature in the metallic state; but of all the substances in which it is recorded to have been found native, the most trustworthy are those in which it was discovered among volcanic products.

The colour of lead is bluish-grey; and when it is cut, the fresh surface has considerable lustre; but this brilliancy disappears in a short time, in consequence of the formation of a thin crust of suboxide.

The lead of commerce is nearly pure, as shown by the analyses given at p. 504; the impurities, often present in very small quantities, are silver, copper, antimony, and sometimes iron and manganese.

Lead is very soft, is easily cut by a knife, and may be scratched by the nail. It readily receives impressions, and leaves a streak on white paper. It is very malleable and ductile, and is capable of being rolled into thin sheets or drawn into wire. It occupies the sixth rank among metals as to malleability, and the eighth rank as to ductility. Rolled lead is more ductile than cast lead, in the proportion of 7 to 5. Its malleability and ductility are much affected by the presence of impurities, especially by the oxide of lead, which it dissolves in small quantities in the melted state.

It is very deficient in tenacity; a wire $\frac{1}{12}$ of an inch in diameter does not support 20 lbs. In this respect, rolled and cast lead are precisely alike; but with the latter the fracture takes place at once, and the ends are clean and granular.

Lead begins to melt at 325° C., and is completely fused at 335° C. (635° F.); at a red heat, it gives off vapours. At a temperature of 50° P., it loses ·005 of its weight in a charcoal-lined crucible, which increases to ·09 as the heat rises to 150° P., whereas galena loses 3·71 per cent.

It crystallises in regular octahedrons. Mongez obtained it in four-sided pyramids by slow cooling; and Marx procured it in fern-like forms, similar to those in which sal-ammoniac crystallises, by allowing a considerable quantity of melted lead to cool until half had solidified, then piercing the crust and running off the fluid portion. By the electro-chemical action of zinc in a solution of acetate of lead, it is deposited in an arborescent form, known under the name of *Saturn's Tree*. Landrin states that, in 1826, he noticed, in a deep mine in Cornwall, cubical crystals of lead which had been deposited on the miner's tools, and had been entirely oxidised. The presence of silver interferes with the crystallisation.

Lead emits a dull sound when struck with a hammer; but when cast in the form of a mushroom, it becomes sonorous.

The specific gravity of lead is, according to Kupffer, 11·3305; Brisson and Herapath, 11·352; Morveau, 11·358; Karsten, 11·3888; according to Berzelius, when in a state of purity, 11·445.

Its specific heat, according to Cooke, is 0·031400. It is an inferior conductor of heat and electricity.

Lead is pyrophoric in a state of fine division. It is usually obtained in this state by heating tartrate of lead in a glass tube as long as any fumes are evolved, when the tube is sealed by a blowpipe. On breaking the tube after cooling, and scattering the powder in the air, it will burn with a red flash.

When lead is melted in contact with the air, the surface is rapidly coated with an iridescent pellicle, which then passes into a yellow oxide. When the temperature is high enough to melt the oxide, it is absorbed by the lead, which loses its lustre and ductility: it becomes brittle, and all the faces of the fracture are dull. It recovers all its original properties by refusion with charcoal.

The action of air and water on lead has been carefully studied by Prof. Miller, from whose account of their combined action we give the following particulars:—This metal undergoes no change in a perfectly dry atmosphere, nor when sealed up in contact with pure water from which the air has been expelled by boiling. It is, however, subject to a powerful corrosion when exposed to the combined action of air and *pure* water. The surface of the lead then becomes oxidised, the water dissolves the oxide, and this solution absorbs carbonic acid, when a film of hydrated carbonate of lead, $2PbHO.Pb^3CO$, is deposited in silky scales. Another portion of oxide is formed, which is dissolved by the water, and thus a rapid corrosion of the metal ensues. This action is materially modified when various salts exist in the water, even when their quantity does not

Digitized by Google

exceed 3 or 4 grains in the gallon. The corrosion is increased by the presence of chlorides and nitrates, but diminished by sulphates, phosphates, and carbonates, the oxide of lead being scarcely soluble in water containing these salts in solution. Acid carbonate of lime is remarkable for its preservative influence; and in consequence of the presence of this salt in most spring waters, they do not act on lead to any serious extent, a film of carbonate of lead being deposited on the surface of the metal, and protecting it from further action.

The action of *water* on lead is very important in a sanitary point of view, as this metal is so constantly employed in making cisterns, pipes, &c. for domestic purposes. Rain-water from the roofs of houses, especially in towns, is sufficiently impure to prevent its action on the metal. The most insoluble salt of lead is the hydrated oxycarbonate (p. 478) which is only soluble to the extent of abont 1 pt. in 4 millions or one-sixtieth of a grain per gallon of water. When a solution of lead is exposed to the air, silky crystals of this hydrated oxycarbonate are formed, and in a few hours the water does not contain more than $\frac{1}{4,000,000}$ of lead in solution. Water, however, which contains much carbonic acid in solution, is very dangerous, as it dissolves the carbonate of lead. When such water is boiled, the carbonic acid escapes, and the carbonate is deposited. Water has generally so much action on lead, that slate cisterns are much safer than those made with lead.

The *non-oxidising acids* do not act upon lead, except when in contact with the air, as already explained in the case of carbonic acid. *Nitric acid* easily acts on lead, even in the cold, forming protoxide, which is then dissolved. Strong *sulphuric acid* converts the lead into sulphate, when the acid is heated to the boiling point. *Hydrochloric acid* has little or no action, but aqua regia converts the lead into chloride. When *arsenic* or *arsenious acid* is heated with lead, arsenite and arsenide of the metal are formed.

Lead is readily oxidised by *cupric oxide*, which is at the same time reduced to the state of cuprous oxide: it also partially reduces the cuprous oxide, but the oxide of lead which is formed retains a portion of the oxide of copper in combination and prevents any further action on the metallic lead.

Nitre acts rapidly on lead at a high temperature, forming a fusible compound of protoxide of lead and potash. The *acid sulphates* also oxidise this metal; but the neutral sulphates and the alkaline carbonates have no action.

Sulphur, *selenium*, *phosphorus*, and *arsenic* combine directly with lead.

Lead also alloys with most of the *metals*; but only imperfectly with copper, titanium, uranium, cerium, cobalt, nickel, and iron.

Extraction of Lead.

Historical Notices. The most abundant and valuable ores of lead possess so many properties likely to attract the attention of uncivilised nations, that it is not surprising to find early mention of this metal. Some authorities think that allusion is made to its metallurgy in the Hebrew word *opher*, in reference to the powder produced by the formation of the oxide on molten lead. The earliest mention of lead is in the well-known passage in the Book of Job; and it is again named as one of the spoils taken from the Midianites in the Book of Numbers. It is also probable that galena was used as a glaze for earthenware in the time of Solomon, from the notice in Proverbs xxvi. It was also one of the articles in which the Phœnicians traded, and which they may have obtained, in part at least, from this country. It was used in the hanging gardens of Babylon, the level of each terrace being covered with sheets of solid lead.

The Romans also worked the ores of this metal both in Spain and in this country. In the former country, the extent of the Carthaginian mining and smelting operations excite our surprise in the present day, and the slags left by them have been re-smelted on a large scale within the last twenty years, while lead cast in Roman moulds—*pigs*, in fact, of the age of Hadrian and other emperors—have been found in Flintshire, Yorkshire, and other localities.

The methods of obtaining the lead from its ores have not undergone any great change, the smelters having adopted the reverberatory or blast furnace as they found the one or the other more suited to the character of the ores of each locality. The one great improvement in the metallurgic treatment of this metal is Pattinson's desilverising plan, which has been followed by the softening process for the hard leads of commerce, especially those of Spain; and we may remark that the only other addition to the ancient methods has been the condensation of the lead fume.

The Ores of Lead. Lead is seldom found native, but there are upwards of twenty ores of this metal known to the mineralogist. Those of practical importance, however, are very few in number, and all the lead of commerce may be said to be

Digitized by Google

procured from five minerals, viz. the carbonate, sulphate, phosphate, arsenate and the sulphide, the latter ore furnishing more of this metal than all the others.

Sulphide of Lead, or *Galena*, is found in the older and more recent strata, and more or less, in every country of the globe. It occurs in veins in the killas of Cornwall, and in the mountain limestones of Derbyshire and the northern counties. In Cardiganshire and Montgomeryshire, it occurs in the strata of the lower Silurian rocks; and the chief deposits of the United States are found in the rocks of the same geological age. It fills veins in gneiss in Saxony; at Sala in Sweden, it is found in granular limestone.

Sulphide of lead occurs also, in combination with the sulphides of antimony and copper, in the minerals *Geocronite*, *Boulangerite*, *Jamesonite*, *Bournonite*.

Carbonate of Lead, or *Cerusite*, occurs in crystals, and in fibrous, compact, and earthy masses. It is frequently found in lodes, and sometimes in beds in sedimentary limestone, generally associated with galena. It is worked in quantity near Aix-la-Chapelle, and in the neighbourhood of Santander in Spain. It is also found in the mines of Cornwall and Devonshire, in Yorkshire, at Leadhills in Anglesey, and at Seven-Churches in Wicklow.

Sulphate of lead also occurs combined with other salts, in the form of *Linarite, Caledonite, Leadhillite.*

Phosphate of Lead, or *Pyromorphite*, occurs generally at the upper parts of lodes, less frequently in layers, and also usually associated with other ores of lead. There are three classes of this ore, viz. such as contain only phosphoric acid; secondly, those containing both phosphoric and arsenic acids; and lastly, those containing lime and fluorine.

The composition of some of the ores of the first class, is given in the following Table:

Locality .	*Leadhills.*	*Poullaouen.*	*Kransberg.*	*Berezov.*

	100·00	100·00	99·63	99·71

This ore is found at Leadhills, and in Cornwall; at Wicklow in Ireland; at Phœnixville, in the United States; and many other localities.

Arsenate of Lead or *Mimetesite* is met with in large quantities at Drygill, in Cumberland, and has been used in the manufacture of flint glass, to which it imparts great brilliancy. It is found at Redruth and other Cornish mines; at Beeralston in Devonshire, and in America, Siberia, &c., generally occurring near the outcrop of the veins. There are three classes of it, similar to those of the previous ore. The following is the composition of a specimen of the ore which contains arsenic acid, analysed by Bergemann:

	From Blanca, Mexico.
Oxide of lead	74·96
Arsenic acid	23·06
Chlorine	2·44
	100·46

The other ores of lead will be found described in these volumes under their respective mineralogical designations.

Metallurgical Treatment of the Ores of Lead. The differences in the nature of the ores of lead, the peculiarities of the localities as to labour, fuel, &c., and the application of the lead afterwards, have all tended to modify the metallurgy of this valuable metal. It would have been more satisfactory to have described all the different plans in detail; but as this would be inconsistent with the limited space which can be devoted to a metallurgical subject in these volumes, we must confine this article to an account of some of the methods adopted for extracting lead from its ores. Various arrangements might also be pursued in this account of the smelting of lead ores, but we prefer the following, in which we will describe—I. Reduction of the Ores. II. Refining of the Lead. III. Softening of Hard Lead. IV. Smelting of the Slags and other Products. V. Condensation of the Lead Fume.

I. Reduction of Lead Ores.

All the ores of lead may be arranged in two classes in respect to their metallurgical treatment, viz. the sulphur and oxygen compounds of lead, and again as to the form of furnaces employed in their reduction, viz. the reverberatory and the blast furnace.

Digitized by Google

1. The Reduction of Sulphur Ores in Reverberatory Furnaces.

The sulphur ores of lead are treated after two different systems in the reverberator furnace, which have been distinguished by Phillips as the *method of double decompos tion* and the *process by affinity*, and these again differ in the details as practised i this country, in France, and in Germany.

The first plan depends upon the reaction between sulphide of lead and oxide of lea as shown in the following equation:

$$PbS + 2PbO = 3Pb + SO^2;$$

or upon the double decomposition when sulphide and sulphate of lead are the const tuents of the mixture, thus:

$$PbS + PbSO^4 = 2Pb + 2SO^2.$$

This process consists in roasting the galena in a reverberatory furnace, until portion of the ore has been converted into oxide and sulphate of lead; it m be performed either in a distinct furnace, or in the smelting furnace where the subs quent fusion is effected. The following table of analyses of roasted ores, from differe localities, illustrates the above remarks.

Analyses of Roasted Galena.

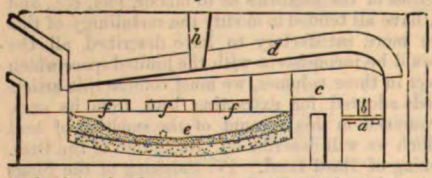
	114	100	100·0	100·0	98·9	99·2

When the roasted ore has been thoroughly mixed, the doors are closed and the fires a set away. The reactions above explained then take place, when the lead is separate This process is applicable to the ores which are comparatively free from silica an earthy impurities, and is generally adopted in England.

The process by affinity consists in fusing the ore with iron in some form or othe when, the iron combining with the sulphur, the lead is eliminated: thus,



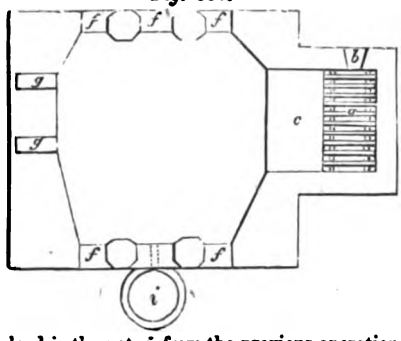
$$PbS + Fe = Pb + FeS;$$

and this plan is better suited to the impure ores of lead.

a. *Method by double Decomposition.*

English Process.—*The Reverberatory Furnace* consists, as usual, of three essenti parts, the fireplace, hearth and chimney. The position and relative proportions of eac part are shown in *figs.* 589 and 59 where *a* represents the grate; *b*, th door of the fireplace; *c*, the fir bridge; *d*, the arched roof; *e*, th hearth; *f f*, the working doors; *g* flues running into one main flu leading to a condensing-chambe and chimney.

Fig. 589.



The hearth is hollow or funnel shaped, to facilitate the descent o the lead to the lowest point in the bed of the furnace. The bottom of these furnaces or hearth, as it is called, is built of bricks, which are covered with a layer of slags These slags are run into a semi-fluid condition by a heavy fire, and then worked int the proper shape by means of paddles and rakes. The hearth slopes more rapidly fro the fire-bridge than from the flue, to prevent the lead being exposed too long to th action of the heated air.

Digitized by Google

There are three working doors on each side of the furnace, attended by two men, who assist each other in manipulating the charge. The lead collects at the lowest part of the hearth, covered by the slags, and is drawn off by a *tap-hole* into the metal pot, *i*, in front of the furnace.

Fig. 590.

The arch falls rather rapidly towards the flues, *g g*, to give more effect to the heat, and the draught is capable of regulation by means of dampers.

The usual charge of ore in these furnaces at Holywell weighs 20 cwt., which is introduced through a hopper, *h*, in the arch of the furnace. This charge is then spread evenly over the surface of the earth, and gently heated for two hours, the doors being closed and the damper lowered.

The two front doors, farthest from the fire, being opened, the smelter throws in the slags swimming on the surface of the lead in the pot, *i*, from the previous operation. The tap-hole is opened in a little time to allow the metallic lead to run off from the slags, and at the same time, an assistant turns over the ore, through the back doors, by means of a paddle. These doors are now closed, while the front ones are open, through which some small coal is thrown in upon the lead-bath, and the whole is worked up together, the ore being turned over with a paddle. The smelter, in about three-quarters of an hour from the commencement, throws back upon the sole of the hearth, the fresh slags, which then float upon the bath, and are mixed with the coaly matter. These slags and the ore are then turned over with the paddle, and all the doors are closed.

The ore is turned over again through the back doors, and the first lead appears, obtained from the slag last remelted. This lead is run off by the tap, and both workmen then turn over the ore, through all the doors. The smelter now closes all the front doors except that next the fire-bridge, and lifts off the fresh slags from the lead pot, drains them, and throws them back into the furnace. The interior of the furnace, at this period, has a dull red heat.

The lead begins to separate from the ore in about 1½ hour from the charging of the furnace, and the two workmen again turn over the ore from each side of the furnace. Some coal is thrown on the grates, slightly to raise the heat, the ore is turned over, and all the doors are closed.

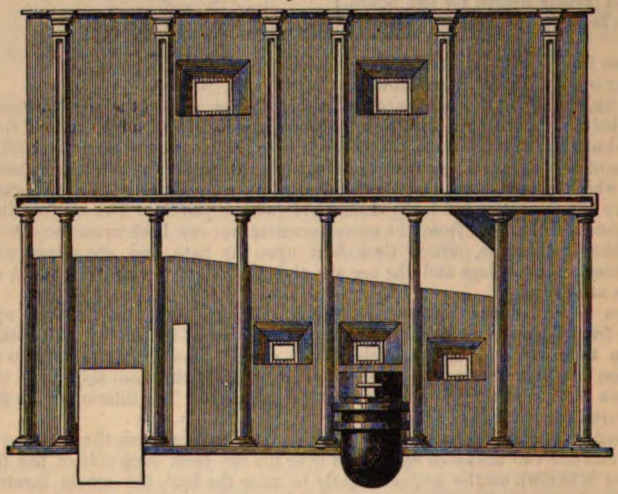
The *first fire* or roasting lasts about two hours, and the damper is then raised a little; coal is thrown on the grates to give the *second fire*, which lasts 25 minutes. The heat of the furnace has now become bright red, and the lead flows from all sides to the bath. The smelter then pushes the slags back towards the upper part of the hearth, while the assistant spreads them over its surface, through the back doors. The smelter now throws in a few shovelfuls of quicklime upon the lead-bath, through the middle door. The assistant works the ore and slags through the three back doors, spreading them out, while the smelter again pushes the slags from the inner bath to the upper part of the sole. The doors are left open for a short time, and the lead flows down into the basin from the slags with which it was mixed as they were pushed back.

The workmen in a short time again turn over the ore and slags, and in three hours from the commencement, a little more fuel is thrown on the grate. In ten minutes, fresh fuel is added for the *third fire*, the damper is fully raised, all the doors are again closed, and the furnace is left in this state for three-quarters of an hour. At the expiration of about four hours, all the doors being opened, the assistant levels the surface to facilitate the separation of any lead, and then spreads the slags which are pushed back towards him by the smelter, who now throws in more lime to render the slags less fluid and to cover the lead-bath.

The smelter adds a fresh charge of fuel in about ten minutes after the completion of the third fire, and closes the doors to give the *fourth fire*. This fire is finished in four hours and forty minutes, when the doors are opened, the tap-hole is pierced to allow the lead to flow into the pot outside, and some lime is thrown upon the slags in the inner bath. The smelter then pushes these *dried* slags towards the upper part of the hearth, whence the assistant rakes them out of the furnace through the back doors.

We have given this detailed account of the working of a charge from Mr. Phillips' excellent description of the process followed in Wales, as an illustration of the nature of these operations, and to avoid the necessity of similar minute details in other analogous processes.

Digitized by Google



The weight of a charge varies in different localities, 12 to 14 cwt. being that used i the north of England; 21 cwt. in Bristol, and 30 cwt. in Cornwall, while the tin extends from 6 to 24 hours, according to the weight and nature of the ore.

The cost of smelting an average parcel of galena in the reverberatory furnace is:

	s.	d.	
Labour	9	7·2	per ton of ore.
Coals 19·9 cwt. . . .	3	3·8	„
Lime 0·9	0	4·9	„
Repairs	0	4·0	„
	13	7·9	

In some smelting works, the roasting process is conducted in a distinct furnace, a in other mills, the two furnaces are combined in the manner shown in *fig.* 591, whi

Fig. 591.

represents the front or tapping side of the furnace. It is unnecessary to give a details of this form, after the description of the previous furnace.

When the process of roasting is conducted in a separate furnace, as a distinct oper tion, the cost per ton, from an average of upwards of 700 tons, is as follows:

	s.	d.
Labour	3	2·5
Coals 5·6 cwt. . .	0	11·2
Repairs . . .	0	1 8
	4	3·5

This is probably the most suitable place to notice the results of some experimen made by Plattner and other chemists, on the loss of silver which occurs during t roasting of ores containing this metal, and which we can confirm from our own experien

1. The loss of silver arises from chemical reactions.

2. The volatilisation of the silver appears to take place at the moment when passes into the metallic state from its combination with sulphur, or when the sulpha of silver is decomposed.

3. The loss of this metal increases with the duration of the roasting, and the rise the temperature.

4. The loss also increases when the oxides of iron or copper are present to deco pose the sulphate of silver.

5. The loss is not so great with the silver-compounds of arsenic and antimonic acid obviously because these salts are not so soon decomposed as the sulphate of silver.

We may also here notice the proposal of Fallizé, to tap the lead at different period instead of doing so at the end of the operation. He founds his proposal on the fa that the lead which is first reduced, is the richest in silver; and by keeping the differe products distinct, the subsequent operation of desilverising would be to some exte anticipated as well as facilitated, by providing leads varying in their richness in silve

Digitized by Google

When the temperature is raised, during the vigorous stirring of the ore, a quanti of lead is liberated, as already explained. Some subsulphide of lead is, however, a formed, which likewise reacts with the sulphate of lead, producing metallic lead; th

$$Pb^2S + PbSO^4 = 3Pb + 2SO^2.$$

During this first period of the operation, lead is continuously liberated, and runs do to the bath in the hearth. The progress of the roasting converts more and more of t sulphide into sulphate of lead, diminishing the liberation of lead until a point reached, when oxide of lead is the only product of the reaction; thus,

$$PbS + 3PbSO^4 = 4PbO + 4SO^2.$$

The second stage of the operation is then in progress, when, by the addition of red-h charcoal and an increased temperature, the litharge is reduced and another portion lead is obtained.

French Process.—When galena is exposed to a continuous and slowly increasi temperature, a large proportion is converted into sulphate of lead, and a smaller p tion into oxide of lead. If the roasting is interrupted at this point and the heat rais but not so high as to induce fusion, these compounds react upon each other, produci oxide of lead, which furnishes metallic lead by the reducing action of coal; thus,

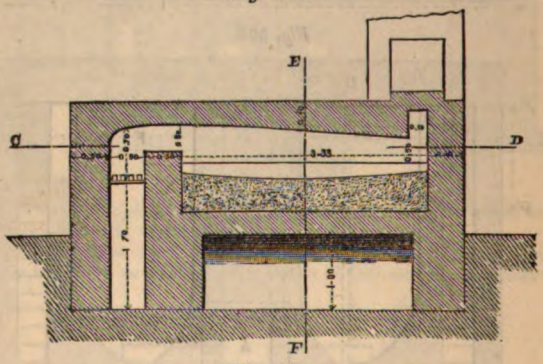
$$PbS + 3PbSO^4 = 4PbO + 4SO^2$$
$$PbO + C = Pb + CO.$$

The coal also reduces the sulphate of lead ultimately into metallic lead and sulphur acid. At a low heat, only half of the sulphate is converted into sulphide of lead; th

$$2PbSO^4 + C^2 = PbSO^4 + PbS + 2CO^2.$$

And as the temperature is raised, the same reaction occurs, as explained in the Car thia process.

Fig. 594.



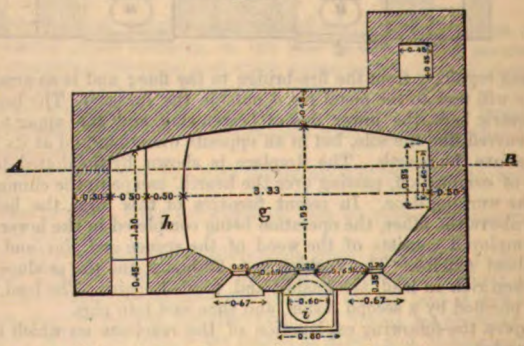


Fig. 595.

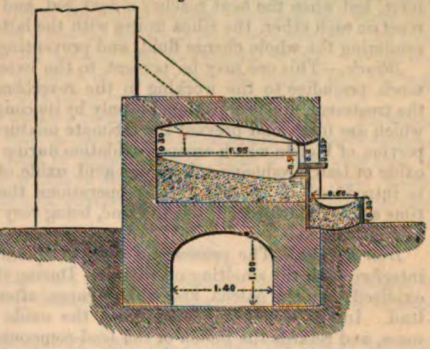

The French process is founded on these reactions, and the furnace employed is r presented by *figs.* 594, 595, 596, the first being a longitudinal, the second a horizont and the third a transverse section.

similar in its action to the carbonate of calcium, with sulphate of barium, towards which substance

Digitized by Google

Quartz, Clay, and Silicates.—These gangues, when present only to the extent of 5 6 per cent., are very injurious, and it is impossible to obtain any lead in the rev beratory furnace, when they amount to 12 per cent. During the roasting they s inert, but when the heat reaches a dark red, and before the sulphide and oxide of le react on each other, the silica unites with the latter, forming very fusible basic silicat rendering the whole charge fluid, and preventing any further action.

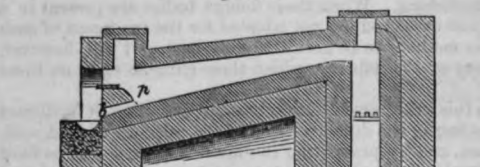
Blende.—This ore may be present to the extent of 10 or even 15 per cent. withc much prejudice to the working in the reverberatory furnace. It does not complic the treatment, and is objectionable only by its conversion into oxide and sulphate of zi which are inert, and prevent the intimate mixture of the lead-compounds. The sm portion of blende which escapes oxidation during the roasting, reacts afterwards on t oxide of lead, producing sulphurous acid, oxide of zinc, and metallic lead. When c is introduced in the subsequent operations, the oxide of zinc is reduced at the sa time as the oxide of lead, and the zinc, being very volatile, carries off a considerable p tion of lead.

Iron Pyrites.—The presence of a small quantity of this mineral does not seriou interfere with the smelting operations. During the roasting, the pyrites is more rapid oxidised than the galena, and what escapes, afterwards assists in reducing the oxide lead. In the concluding operations, the oxide of iron is disseminated through t mass, and retards the fusion of the lead-compounds. A large proportion of pyrites however, very prejudicial, as that portion which is unoxidised, forms a very fusib matt with the sulphide of lead, which escapes the reduction.

When the pyrites is arsenical, the lead is always rendered more or less impure the presence of arsenic, which increases the loss of both lead and silver in the subs quent cupellation.

Sulphide of Antimony.—This ore is always very injurious, even when present on to the extent of 2 or 3 per cent. It gives rise to the same reactions as galena; and portion of the antimony being brought to the metallic state, combines with the lea rendering the latter hard, and occasioning a loss of both lead and silver when submitt to cupellation. The compounds of antimony also form very fusible compounds wi those of lead, which cannot then be brought to the metallic state. The great volatili of antimony, its oxide and sulphide, also increases the loss of lead and silver.

Copper Pyrites.—This mineral renders the ores unfit for treatment in the reverberato furnace. Even when it is present in such small quantities as not to interfere with t reactions, the lead always retains a portion of the copper, which diminishes its co mercial value.



Carbonate of Iron.—This substance acts only as a mechanical hindrance in the fu nace, where it is gradually converted into oxide of iron. During the later period of t operations, it retards the fusion of the slags, and postpones the reactions until near all the sulphide of lead is oxidised. This gangue therefore, when present in sm quantities, is favourable rather than otherwise in the reverberatory furnace.

b. *Process by Affinity.*

This plan was used in France for treating a Spanish galena which contained a lar proportion of quartz, and is founded on the reactions already explained.

The furnace employed is shown in *fig.* 597, and is charged with about 800 lbs. ore through a side door. Th charge is mixed with 200 240 lbs. of iron, which oug to be in the form of scrap iro as cast iron, mill cinder, a iron ores are not found to a swer equally well with small able iron. The mixed char is then rapidly heated unt the galena begins to softe when the temperature is ke stationary to permit the r actions to take place. Th lead, as it is reduced, flows to the lower part of the furnace at *p*, while the matt swi on the surface, and this again is covered by the slag. The contents are then drawn o through the tap-hole *b*, into the metal pot.

Fig. 597.

A modification of this plan has been proposed by Phillips and Rivot, who employ furnace with a hearth slightly inclined towards a basin at the side, placed before on of the two side doors.

The furnace is to be charged with 1600 lbs. of ore, which must be carefully spre

The ore smelted in these furnaces contains carbonate of lead and galena, mixed oxide and carbonate of iron, oxide of antimony, carbonate of lime, clay and sa This ore is used raw, mixed with lead-slags, and coke is the fuel employed.

The furnace having been annealed for some hours, 3 or 4 pigs of lead are place the hearth to form a bed for the slags, and the furnace is charged with coke. or 6 hours, a few baskets of slags are thrown in with a little granulated iron. A a little time, the slags begin to run down the incline, when the regular charge of is added. The air-holes are regularly watched to keep them all at the same de of heat, as any neglect is apt to allow the materials to harden, when these air-tuy become choked. It is in fact the duty of one man to remove all the *niggers* or black lumps, which tend to form in and near them. The furnace is charged only every hour, as the opening of the charging door, D, injures the draught.

The charge consists of:

	40 baskets of ore, or about 5 cwt.	
8 to 10	„	old Slag.
4 to 5	„	coke, with some dry wood.

The latter assists in diffusing the air uniformly through the materials. The quant used in 24 hours are:

Ore	cwt. 134	Coke	cwt. 20
Slag . . .	44	Wood	„ 2

Digitized by Google

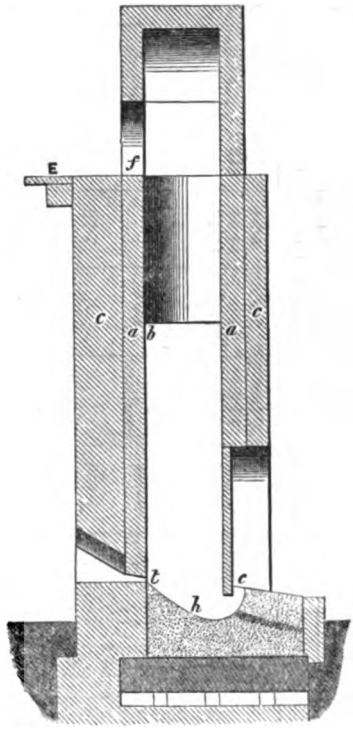
As the air has a tendency to ascend round the sides of the furnace, the smelter throws his charges against the walls, and keeps the air-channels as far as possible open to the centre of the furnace. When the furnace becomes *gobbed* in any part, one or more of the register-holes are opened to enable the smelter to remove the obstruction.

The lead is tapped every six hours, and the matt is returned to the furnace. The produce varies from 6 to 7 cwt. of lead upwards, according to the richness of the ore.

We have described this furnace at some length, as it is cheaply built, lasts about 6 to 8 weeks, and can be used in localities where more perfect plans would be impracticable.

2. The Reduction of Lead Ores in Blast Furnaces.

The ores generally smelted in blast furnaces are such as, from the proportion of their impurities, are not adapted to the reverberatory furnace; but this remark does not apply to the peculiar form of blast furnace known under the name of the ore-hearth, as used in America and this country (p. 497).



a. *The Cupola or Blast Furnace.*

This form of furnace is very generally adopted on the Continent, and exhibits at different works a great variety of form and dimensions. The great difference in the ores, the fluxes available and the nature of the fuel, are all so many conditions which require special modifications to overcome the difficulties peculiar to each locality.

We will select, as illustrations of this mode of smelting, three of the modifications in which the ore is used in the raw and roasted form, and in both states.

Silesian Furnace.— The form and construction of this furnace are represented in *fig.* 601. The walls, *a a*, are vertical from the tuyere upward; for a distance of 10 feet 4 inches to 6 feet, the section of the furnace is rectangular, while above this point it takes a circular form. The exterior wall, *c c*, is built of common bricks, and the lining or *skirt*, *a*, is constructed of fire-bricks. The charge of raw ore and flux is mixed on the floor, E, and thrown into the furnace through the opening *f*. The blast enters at *t*, and fusion takes place, during which the hearth, *h*, is gradually filled with the lead produced. The slag floats on the surface of the lead, and is drawn off at *c*, while the lead is occasionally tapped through a canal which passes to the bottom of the hearth. The fume is carried away from the top of the furnace through a series of condensing chambers. These furnaces can only be worked for about eight days, when the operation is stopped to repair the lining.

Fig. 601.

The *lit de fusion* consists of:

Galena in small pieces . .	100 parts.
Cast iron	12 ,,
Slag from iron forge . .	14 ,,

Each ton of this charge requires a ton of coal, which is thrown against the front, and the ore, &c. against the back of the furnace.

When the slag contains 7 or 8 per cent. of lead it is resmelted. The matt or regulus, consisting of sulphide of iron and lead, with a little silver, is roasted and smelted in the same furnace.

Harts Furnace.—This plan is adopted in the Hartz, France, and Belgium, more or less modified according to the circumstances of the locality. The ore is always submitted to previous roasting; and when this operation is performed in a reverberatory furnace, the heat is gradually raised, until the oxidation is sufficiently advanced, when the doors are closed. The fire is then urged to melt the mass of materials, which is then drawn, allowed to cool, and broken up into pieces fit for charging the blast furnace.

The following tables contain numerous analyses of the matt and slags which are obtained from the blast furnaces of France and Germany.

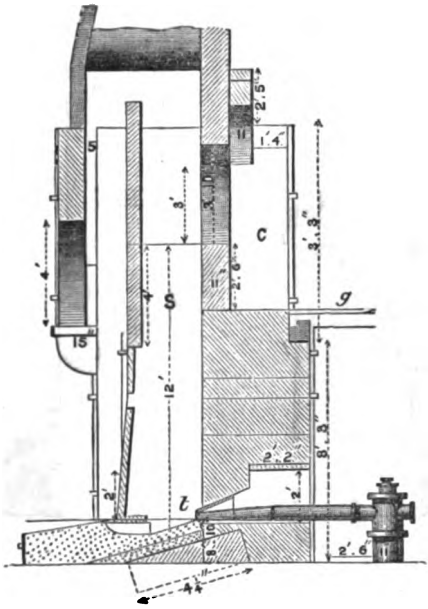
The ore is sometimes roasted in the open air, as at Rammelsberg, on the Hartz, a Fahlun in Sweden. The ore at the former place, consisting of an intimate mixture the sulphides of lead, copper, iron and zinc, is formed into heaps, as seen in *fig.* 602

Fig. 602.



A thick layer of pine wood, *a a a*, is laid down for a foundation, upon which the o *b b*, is placed in pieces decreasing in size towards the top. The whole is covered wi a layer of roasted ore in powder, which shuts off the access of an excess of air. The heaps contain about 150 tons of ore, and after they are ignited, the combustion is su ported by the sulphides, through a period varying from 18 to 24 weeks.

At the top of the pile are a number of cavities, *s s s*, formed in the porous coverin in which a portion of sulphur collects, as it is sublimed from below, and from whi it is ladled at times. A ton of sulphur is usually obtained from a heap, and it is sa nearly to pay the cost of roasting. The metallic products are afterwards roasted in second and third heap.

Digitized by Google

This roasted ore is smelted in a furnace constructed as shown in *fig.* 603. The charge is prepared on the floor, *g*, and thrown into the furnace, *s*, through the opening *c*, along with the fuel. A strong blast is driven in through the tuyere, *t*.

Fig. 603.

The charge consists of

Roasted ore	35	cwt.
Highly siliceous slags	10	,,
Oxide of lead and pieces old cupels .	¼–½	,,

The matt is repeatedly roasted and resmelted to obtain any copper, lead and silver, it may contain.

Spanish Economic Furnace. The discovery of enormous deposits of slags left by the Romans, near Cartagena and other places in Spain, together with the mining of a poor lead ore in these districts, has led, within the last 15 or 20 years, to a very great development of lead smelting on this coast. Furnaces of different descriptions were tried, one after another, but they have all given place to what is known under the above name.

This furnace, as improved by the writer, is represented in *figs.* 604, 605, 606, in elevation, section and plan. The blast enters through three water-tuyeres, *a a a*, and the materials are maintained up to the level of the charging door, *b*. The upper layers are kept cool by a fine rain of water from a rose, *c*, and the steam which is formed assists in condensing the fumes which escape into the flue, through an opening, *d*, in the back side of the top of the furnace. The upper part of the furnace rests upon four metal pillars, *ffff*, so that when the body of the furnace requires to be renewed, this part remains untouched. The lead accumulates in the hearth, *g*, whence it is tapped, from time to time, into the pot, *h*, to be ladled into moulds. The slag runs continuously into a tank, *i*, which is kept supplied with a stream of water. The slag in this case falls into a coarse sand, which is easily carted away, but it is sometimes run into small waggons, forming large blocks on cooling.

The furnace is circular, with a diameter of from 2¼ to 2½ feet, and built of fire-bricks moulded to suit the form of the furnace. The body of the furnace is only one brick thick, and when any portion of the wall gives way, the hole is filled with clay, which is driven into the interior, while the smelter lays fresh bricks to rebuild the wall.

The bottom of the furnace is formed in Spain of a kind of clay which is found to answer remarkably well, but in this country a mixture of pure ground coke and fire-

Digitized by Google

clay is employed. This mixture, made into a paste, is very carefully beaten down, then the hearth is cut out, as shown in the figure (605). The formation of this bo

Fig. 604.

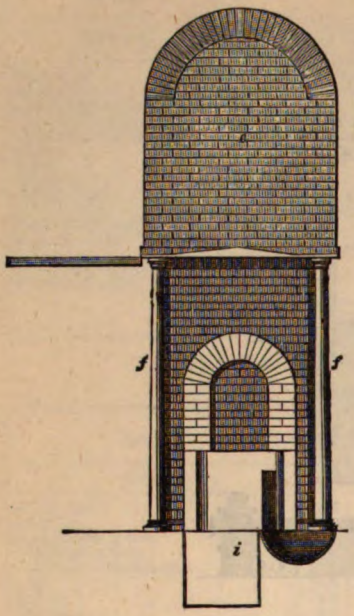


Fig. 605.

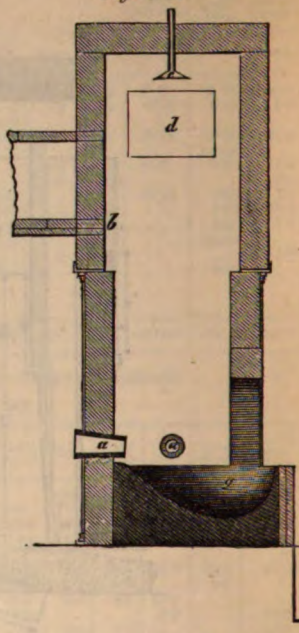

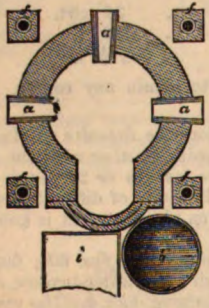

Fig. 606.

requires the greatest care, as the duration o furnace depends more upon its stability than the continuance of the walls, which, as alr explained, can be repaired from the outside.

The breast of the furnace is made of a s circular plate of cast iron, with a lip to carr the slag, and a slit through which the tapho drilled. Above the breast-pan is an arch a 18 inches wide and 24 in height.

The materials are charged, layer upon l of ore and flux and coke. The ore may be ei raw or roasted, and the nature of the flux pends upon the character of the gangue. In S the ore is sometimes roasted in kilns, consis of large chambers, something like our fire-b kilns. The ores or materials containing lea be smelted in this furnace should not hold r than 20 or 30 per cent. of lead.

When this form of furnace was introduced into this country, the writer made a g number of experiments as to the ores and fluxes which could be most profitably sme by it; but it would be impossible to give the details in so limited an article as present. It may, however, possess some interest to give the materials smelted the cost of one of the first campaigns, which term is employed to designate the t the furnace works without being rebuilt. This campaign lasted 15 weeks, work night and day, and the following weights of ores were smelted:

Spanish ore . . .	3249·50 cwt.	English lead ore slags .	1521·25 cw
English lead ores .	8634·60 „	Litharge . . .	30·50 „
American silver ores .	86·75 „	Litharge cinders . .	973·75 „
			14496·35

There was a gain of silver on the assays, but a loss of lead of about one-tenth on

Digitized by Google

assays, which, however, it is proper to say, were made most carefully by the best methods. The cost was as follows:

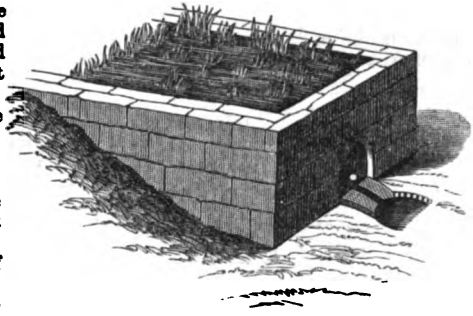
							per ton. s.	d.
1. Wages connected with the furnace					£124	1 9	= 3	5·1
2. Engine power: wages		£10	10	1				
1509 cwt. coals		12	11	6	23	1 7	= 0	7·5
	cwt.							
3. Fluxes, Fluor spar	228½	9	15	0				
Carbonate of baryta	14	1	2	6				
Chalk	209½	0	16	2				
Limestone	250	3	13	0				
Rock-salt	144½	6	11	8				
Kelp	5	0	10	0				
Hematite ore	25	0	18	9				
Metal borings	790	79	15	0				
Mill cinder	4673	40	18	3				
Grey slags	704	1	15	9				
Pitch	5	0	1	3				
Coal	19	0	3	2	= 146	0 6	= 4	0·3
4. Fuel—Coke	2667				47	16 1	= 1	3·8
5. Repairs					33	1 0	= 0	10·9
					£374	0 11	= 10	3·6

The following statement contains the cost of smelting the Roman slags near Cartagena, in Spain, calculated on the produce of lead:

Cost of 20 cwt. of Lead.

360 quintals at 8 per cent. lead, washed up to 24 per cent.

= 120 quintals for smelting		360 reals
30 „ of coal for engine, at 6 reals		180 „
50 „ of coke for smelting, at 11 reals		550 „
2 smelters, at 8 reals		16 „
4 labourers, at 6 reals		24 „
Wear and tear		50 „
Management, &c. &c.		100 „
		1280 reals



and this expense, at 92 reals per £ sterling, brings the cost of a ton of lead up to £13 6*s.* 8*d.* per ton, where the Roman slags are obtained free of charge.

We believe this form of furnace is admirably adapted for many of our poorer ores and materials containing lead, and that it well deserves the attention of our smelters.

b. *The Ore-hearth.*

This method of reducing can only be applied to the purest description of ores, and the advantage which it possesses over the reverberatory furnace, consists chiefly in the greater purity of the lead which is produced. This, however, is of great commercial importance, as such lead is suitable for conversion into the best white and red leads, and in consequence brings £1 per ton more in the market than ordinary soft lead. The ore hearth is also worked with less consumption of fuel and a smaller outlay in labour. The cost of the furnace is much less and the working may be discontinued and resumed at any time without repairs being required.

Fig. 607.

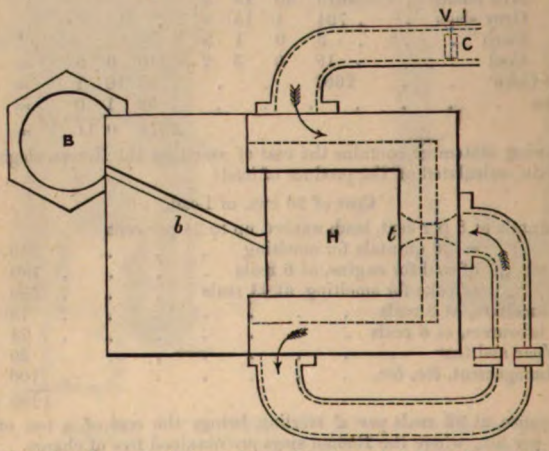
The first construction to be noticed is that of

The Backwoods Hearth.

This form of furnace is of the most primitive character, and yet the practice of the Western backwoodsman is still more simple; if he wants shot or bullets, he kindles a fire in a hollow tree, or an old stump of a tree, places some galena on the charred wood, and melts it down, when after cooling, he finds the metal at the bottom of the hollow.

In Missouri, the ore was reduced in square furnaces, constructed of logs or stones, as shown in *fig.* 607.

Digitized by Google



The air is admitted through the arch in the fore-side, and the lead is collected in basin in front. The management consists in placing a layer of heavy logs at bottom; then billets of split wood are set upright, on which the galena is thrown, top of the ore being covered with small wood. A fire is kindled in the front a which chars the lower portion of the wood, and the process of reduction commen The lead runs into the basin, and the operation lasts 24 hours. The ashes are colle after the furnace cools, and they are smelted in what is called an *ash-furnace.*

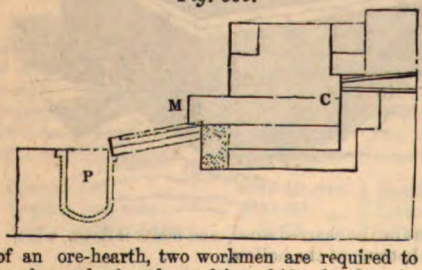
This plan is now superseded by constructions of a modern type.

The American Hearth.

This furnace (*fig.* 608) is sometimes made of cast iron, and so arranged that a hollow surrounds the hearth, H, through which the air passes on its way to the tuyere, by wh contrivance the blast is raised to a high temperature. The air enters through the p C, and, following the course of the arrows, is driven through the tuyere into the hea

Fig. 608.

As the ore is reduced, the lead flows down the channel, *b*, into the pot, B. The f of the blast can be regulated by the valve, V.



The hearth is first carefully warmed by a wood fire, when the reservoir in the hea H, is filled with lead, which soon melts, and upon which the charge floats during operation. The smelter places several pieces of wood before the blast, and then cha with raw galena. The whole soon becomes heated, the reduction follows, and lead flows off into B. The first charge is followed by another, and thus the proce continued as long as the smelter wishes.

At Rossie, in New York, 75 cwt. of lead is obtained in 24 hours, and the cos working is about seven shillings per ton.

The Scotch Hearth

is in use in the northern counties of this country, and Mr. Phillips' account of mode of working it, is so admirable that we cannot do better then quote it.

Fig. 609.

This furnace (*fig.* 609) is f 22 to 24 inches in height, and 1 18 inches area inside, but its h zontal section, always rectangu varies much in its dimensions different levels.

The ore can be worked eithe a raw or roasted state, but the la is now generally used, as it yiel better produce, and works dry, lowing the blast to diffuse itself n perfectly through the mass.

In proceeding to smelt by me of an ore-hearth, two workmen are required to be in attendance from the beginn to the end of each smelting shift, the duration of which is from 12 to 15 ho The first step in commencing a smelting shift is to fill up the hearth-bottom

Digitized by Google

space below the workstone with peats, placing one already kindled before the nozzle of the bellows. The powerful blast very soon sets the whole in a blaze, and by the addition of small quantities of coal at intervals, a body of fire is obtained, filling the hearth. Roasted ore is now put upon the surface of the fire, between the forestone and pipestone, which immediately becomes red-hot and reduced, the lead from it sinking down and collecting in the hearth-bottom. Other portions of ore, of from 10 or 12 lbs. each, are introduced from time to time, and the contents of the hearth are stirred and kept open, being occasionally drawn out and examined upon the workstone, until the hearth-bottom becomes full of lead. The hearth may now be considered in its regular working state, having a mass of heated fuel, mixed with partly fused and semi-reduced ore, called *browse*, floating upon a stratum of melted lead. The smelting shift is then regularly proceeded with by the two workmen, as follows:—The fire being made up, a stratum of ore is spread upon the horizontal surface of the browse, and the whole suffered to remain exposed to the blast for about five minutes. At the end of that time, one man plunges a poker into the fluid lead in the hearth-bottom below the browse, and raises the whole up at different places, so as to loosen and open the browse, and in doing so, to pull a part of it forwards upon the workstone, allowing the recently added ore to sink down into the body of the hearth. The poker is now exchanged for a shovel, with a head 6 inches square, with which the browse is examined upon the workstone, and any lumps that may have been too much fused, are broken to pieces; those which are so far agglutinated by the heat as to be quite hard, and further known by their brightness, are picked out, and thrown aside, to be afterwards smelted in the slag hearth. They are called "grey slags." A little slaked lime in powder is then spread upon the browse, which has been drawn forward upon the workstone, if it exhibit a pasty appearance; and a portion of coal is added to the hearth, if necessary, which the workman knows by experience. In the meantime, his fellow-workman, or shoulder-fellow, clears the opening through which the blast passes into the hearth, with a shovel, and places a peat immediately above it, which he holds in its proper situation, until it is fixed, by the return of all the browse from the workstone into the hearth. The fire is made up again into the shape before described; a stratum of fresh ore spread upon the peat; and the operation of stirring, breaking the lumps upon the workstone, and picking out the hard slags repeated, after the expiration of a few minutes, exactly in the same manner. At every stirring a fresh peat is put above the nozzle of the bellows, which divides the blast and causes it to be distributed all over the hearth; and as it burns away into light ashes, an opening is left for the blast to issue freely into the body of the browse. The soft and porous nature of dried peat renders it very suitable for this purpose; but in some instances, where a deficiency of peats has occurred, blocks of wood of the same size have been used with little disadvantage. As the smelting proceeds, the reduced lead, filtering down through all parts of the browse into the hearth-bottom, flows through the channel, out of which it is laded into the pig-moulds.

The principal particulars to be attended to in managing an ore-hearth properly during the smelting shift are these: First:—it is very important to employ a proper blast, which should be carefully regulated, so as to be neither too weak nor too powerful. Too weak a blast would not excite the requisite heat to reduce the ore, and one too powerful has the effect of fusing the contents of the hearth into slags. In this particular, no certain rules can be given; for the same blast is not suitable for every variety of ore. Soft, free-grained galena, of great specific gravity, being very fusible, and easily reduced, requires a moderate blast; while the harder and lighter varieties, many of which contain more or less iron, and are often found rich in silver, require a blast considerably stronger. In all cases, it is most essential that the blast should be no more than sufficient to reduce the ore, after every other necessary precaution is taken in working the hearth. Secondly:—The blast should be as much divided as possible, and made to pass through every part of the browse. Thirdly:—The hearth should be vigorously stirred at due intervals, and part of its contents exposed upon the workstone, when the partially fused lumps should be well broken to pieces, and those which are farther vitrified, so as to form slags, carefully picked out. This breaking to pieces, and exposure of the hottest part of the browse upon the workstone, has a most beneficial effect in promoting its reduction into lead; for the atmospheric air immediately acts upon it, and, in that heated state, the sulphur is readily consumed, or converted into sulphurous acid, leaving the lead in its metallic state; hence it is that the reduced lead always flows most abundantly out of the hearth immediately after the return of the browse which has been spread out and exposed to the atmosphere. Fourthly:—The quantity of lime used, should be no more than is just necessary to thicken the browse sufficiently, as it does not in the least contribute to reduce the ore by any chemical action; its use is merely to render the browse less pasty, if, from the heat being too great, or from the nature of the ore, it has a disposition to become very soft. Fifthly:—

Digitized by Google

Coal should be also supplied judiciously, too much unnecessarily increasing th the browse and causing the hearth to get quite full.

When the ore is of a description to smelt readily, and the hearth is well ma every particular, it works with but a small quantity of browse, which feels d stirred, and is easily kept open and permeable to the blast. The reduction rapidly with a moderate degree of heat, and the slags produced are inconsidera if in this state, the stirring of the browse and exposure upon the workstone ar tinued, or practised at longer intervals, the hearth quickly gets too hot, mediately begins to agglutinate together, rendering evident the necessity operations to the successful management of the process. It is not difficult to un why these effects take place, when it is considered, that in smelting by mea ore-hearth, it is the oxygen of the blast and of the atmosphere which principall plishes the reduction; and the point to be chiefly attended to, consists in exp ore to its action, at the proper temperature, and under the most favourable stances. The importance of having the ore free from impurities is also eviden stony or earthy matter it contains impedes the smelting process, and incre quantity of slag. A very slight difference of composition of perfectly dressed be readily understood to affect its reducibility; and hence it is that ore from veins, or the same vein in different strata, as before observed, is frequently work very differently when smelted singly in the hearth. It happens, theref with the best workmen, some varieties of ore require more coal and lime, and degree of heat, than others; and it is for this reason, that the forestone is made so as either to answer for ore which works with a large or a small quantity of

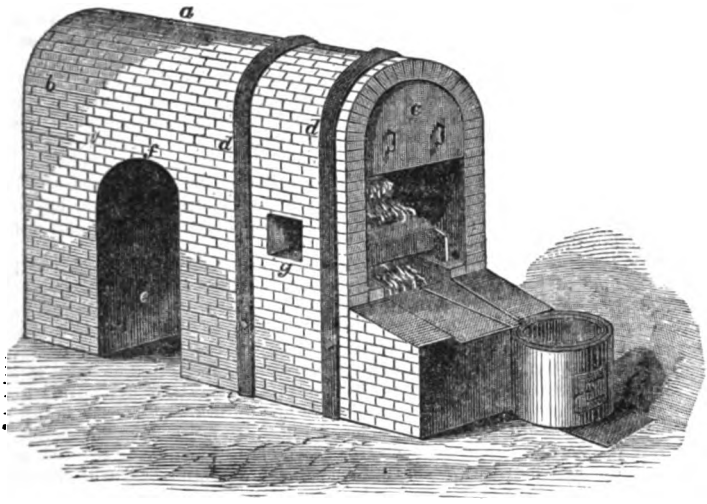
It has been stated that the duration of a smelting shift is from 12 to 15 the end of which time, with every precaution, the hearth is apt to become too it is necessary to stop for some time, in order that it may cool. At mills w smelting shift is 12 hours, the hearths usually go on 12 hours, and are suspe four and a half or five bings* of ore (36 to 40 cwt.) are smelted during a shift, two men who manage the hearth, work each four shifts per week, terminati week's work at 3 o'clock on Wednesday afternoon. They are succeeded by t workmen, who also work four 12-hour shifts, the last of which they finish at on Saturday. In these 8 shifts, from 36 to 40 bings of ore are smelted, which, good quality, produce from 9 to 10 fodders of lead. At other mills, where th 14 or 15 hours, the furnace is kindled at 4 o'clock in the morning, and work 6 or 7 in the evening each day, six days in the week; during this shift, 5 or of ore are smelted, and two men at one hearth, in the early part of each we three such shifts, producing about 4 fodders of lead; two other men work each in the latter part of the week, making the total quantity smelted per week hearth from 30 to 33 bings.

Hearth-ends and Smelter's fume.—In the operation of smelting, as already d it happens that particles of unreduced and semi-reduced ore are continually expel the hearth, partly by the force of the blast, but principally by the decrepitatio ore on the application of heat. This ore is mixed with a portion of the fuel made use of in smelting, all of which are deposited upon the top of the smeltin and are called hearth-ends. It is customary to remove the hearth-ends from time and deposit them in a convenient place, until the end of the year, or som period, when they are washed to get rid of the earthy matter they may con the metallic portion is roasted at a strong heat, until it begins to soften an into lumps, and afterwards smelted in the ore-hearth, exactly in the same wa undergoing that operation for the first time, as already described.

It is difficult to state what quantity of hearth-ends are produced by the sm a given quantity of ore, but in one instance, the hearth-ends produced in smelt bings, on being roasted and reduced in the ore-hearth, yielded of common lead and the grey slags separated in this process gave, by treatment in the slag-h cwt. of slag lead, making the total quantity of lead 362 cwt., which is at the 3 cwt. 2 qrs. 23 lbs. from the smelting of 100 bings of ore.

The cost of smelting well-dressed galena at the ore-hearth is as follows:

			s.	d.
Labour			6	1·9
Coals 2·2 cwt.			0	4·4
Wood 1·2 „			0	9·1
Lime 0·6 „			0	3·5
Repairs			0	1·7
Engine Power:	Wages	0 10·7		
	Coals 5·2 cwt	0 10·4	=1	9·1
			9	5·7



* 1 bing = 8 cwt.

Digitized by Google

The ore-hearth, as usually constructed, often allows the fumes to fill the mill, whenever the draught is defective, and thus proves injurious to the health of the work people. Under all circumstances, a large volume of air passes into the flue, and so far diminishes the condensation of the lead-fume.

In order to diminish the objection, the writer introduced the following modifications, shown in *fig.* 610.

Fig. 610.

The hearth is covered with a hood of brick-work, *a*, at the back of which there is an opening into the flue. This opening can be enlarged or diminished by means of a damper, worked from the outside at *b*. The opening in front can also be regulated by means of a movable iron plate, *c*, which can be raised or lowered according to circumstances. The hood is firmly bound by iron straps, *d d*, which are maintained in position by screw-bolts above and below the hearth. The opening *e*, under the arch *f*, allows the workman to regulate the blast, which is admitted at the back through the ordinary tuyere.

The ore is charged through the opening *g*, in the side of the hood, and the furnace is worked from the front, in the manner just described.

We have now finished our account of the reduction of lead ores, and regret that we are compelled to omit many details relating to the various modifications adopted in Germany and elsewhere, which are treated at great length in Kerl's valuable *Handbuch der Metallurgischen Huttenkunde*, to which we beg to refer the reader for further information.

Chemical Reactions in the Blast Furnace.

The substances which compose the charge in blast furnaces, are generally either in the form of powder more or less fine, or in masses more or less fused.

The fume is in the form of powder, and consists chiefly of carbonate and sulphate of lead. The dross and lead skimmings are in coarse powder, and contain oxide of lead, and some metallic lead mixed with the ashes of the fuel and other earthy matters. The furnace-waste contains quartz, clay, and silicate of lead; while the test-bottoms consist either of silicates of lead, &c., or of phosphate of calcium and oxide of lead. The ores and the grey slags are very varied in their composition, containing sulphide and oxide of lead, sulphates and silicates of lead, calcium, barium, &c., and differ as much in their mechanical condition.

The chemical reactions resulting from the fusion of so varied a mixture of compounds, are necessarily of a very complex character, and change even in the different parts of the furnace; thus in the

Upper Zone.—The uncombined oxide of lead, which happens to be present in the furnace in the form of powder, or as a porous mass, is reduced, and as this lead trickles down to the hearth, a considerable portion is volatilised. It is necessary, therefore, in roasting ores, &c., to raise the temperature high enough to fuse them into masses, which are only acted upon, on the surface, by the reducing gases in the upper part of the furnace.

Digitized by Google

The sulphide of lead is not easily decomposed by the aqueous vapour, and r
the lower zone almost unaffected. The sulphate of lead stands in the same relat
The compounds of iron, on the contrary, undergo a striking change, and in fac
the part of reactives in the lower zone, in consequence of their reduction in this
the furnace. A high furnace is necessary to complete this reduction, but such a f
would be unsuitable for lead for the reasons previously given. The size of the
of these iron compounds, must therefore be regulated by the height of the furnace,
smaller as the furnace is lower.

Lower Zone.—The matters thus prepared in the upper zone, soften, and gra
enter into fusion as they descend, undergoing very complicated chemical changes
are difficult to regulate, and in which the reducing gases exercise little actio
where the solid fuel comes into operation.

The favourable working of the furnace is also assisted, inasmuch as the materi
not all equally fusible, and do not all soften at the same time. The matters cont
the oxide of lead and the slags, melting first, gradually absorb the gangues and p
silicates rich in lead. The sulphates are rapidly decomposed by the melted sil
and they produce very little sulphides under the reducing action of the solid fuel
sulphide of lead present, mixes with the metallic silicates, the reduction of the
compounds commencing only after the formation of the silicates. The reducing
is due chiefly to the metallic iron and solid fuel, the sulphides of barium and c
also assisting in the production of the metallic lead.

Action of the Iron.—This metal decomposes part of the oxide and sulphide o
forming sulphide of iron and oxide of iron, which combines with the silicates.
sulphide of iron acts energetically on the silicate of lead, producing sulphurou
protoxide of iron, and metallic lead. When the roasting has been complete, t
little or no matt formed, and when a sufficient supply of iron has been produ
the upper zone, the lead is all precipitated and the slags then contain no oxide o

The solid fuel assists the action of the iron, but its contact is of course muc
intimate than that of the metal, which ought therefore to be always present in th
portion of an equivalent for every equivalent of lead. Under such circumstanc
slag is very fusible, and does not contain particles of lead, which being reduced
lower zone the loss by volatilisation is as small as the volatile nature of this
permits.

The important point consists in the reduction of sufficient iron in the upper
without necessitating the employment of a very high furnace. In a *lit de fusio*
taining 40 per cent. of lead, there ought to be 9 per cent. of iron in the metallic
or an equivalent quantity of iron ore.

Iron borings, cast iron, &c. have been used, but the proportion of this metal
still be in equivalent quantities to the lead, and they do not act so well as iron
divided, produced by the reduction of the iron ores.

Action of the Coke.—The reducing action of the solid fuel may be made to ta
place of the iron, but unless the gangues and other substances contain sufficient
of iron to produce a fusible slag, the latter will consist only of earthy bases, req
a high temperature for fusion, and thus increasing the loss of lead by volatilisa

Coke has no action on the sulphide of lead, and as the fuel is charged in large
its reducing action is limited to surface contact. The fuel should therefore be re
to powder, and intimately mixed with the *lit de fusion*, while the roasting of the
compounds should be as complete as possible. This latter operation would, ho
require a long time, and its expense would prove a great objection. We made
experiments on this subject, and found that it required upwards of thirty
roasting to bring the sulphur, in pure galena, down to 4½ per cent.

The employment of the fuel in powder, is also attended with the inconvenienc
great heat at the furnace-mouth, and the reduction takes place high above the t
which causes a great loss of lead and silver by volatilisation. It is necessary
fore to employ very low furnaces, and to conduct the fusion very slowly; but w
the aid of the iron there is always an increased loss of lead, when the reduction de
upon the fuel, and with such furnaces, the iron-compounds act simply as fluxes.
the contrary, in a furnace of suitable height, the intimate mixture of the iron or
the fuel, is very effective, the whole of the metal acting as a reducing agent.

The reducing action of the fuel is attended with another difficulty, as it facil
the conversion of the sulphates into sulphides, which then go to form more o
matt. In the case of the sulphates of baryta and lime, the reducing action
fuel is however, to some extent, beneficial, as these substances assist in decomposi
oxide of lead.

When the matts are poor in lead and silver and not in large quantity, their pr
is not very objectionable. We have often worked a furnace where the matt cont
only 1·1 per cent. of lead, and 10 dwt. 10 grs. silver per ton. They indicate, whe

Digitized by Google

either imperfect roasting in the lead-compounds, or a deficiency of the reducing agents, sulphides of iron, barium, or calcium.

Iron Pyrites as Reducing Agent.—This mineral should be previously roasted to expel a portion of the sulphur, when it is to be used in the blast-furnace, but its employment has a tendency to increase the formation of matt. The same effect is produced to a greater extent, when the galena employed is loaded with pyrites, since these two sulphides enter into combination in the upper zone of the furnace, and the matt produced does not act so vigorously upon the silicates as the sulphide of iron alone. The matt therefore partly escapes decomposition, and the quantity is accordingly increased.

Fume.—This substance, being in the form of powder, ought not to be charged direct, but it should undergo a preliminary treatment in a reverberatory furnace. It is advisable to mix it with some lead-compounds and a quantity of sand, varying from 15 to 20 per cent., according to its contents in lead. The charge is rapidly heated to the point of fusion, and about 8 per cent. of fuel, in small pieces, added. The whole is then well worked, to mix the fuel as intimately as possible, which promotes the separation of the lead obtained by the reduction of the silicate of lead.

Action of the Gangues. *Carbonate of iron.*—This substance is converted, more or less, into sesquioxide of iron during the roasting process, and only interferes with the oxidation of the galena when present in large quantities. It acts in the furnace in the manner already explained, and must be regarded as a useful impurity; but when present in larger quantities and intimately mixed with the lead ores, it prevents the agglomeration of the powder, even when sand is added. Under such circumstances, the reducing action must be moderated in the upper zone of the furnace, and the union of the oxides of iron and lead with some fusible siliceous slags, must be promoted. The furnace ought to be low, and driven with a gentle blast; but with all precautions, there is a tendency to *gob* the furnace.

Iron pyrites.—When this mineral is present, the roasting requires a longer time, and it is difficult to prevent the agglomeration of the ores, with an undue formation of sulphates. Towards the end, the heat must be raised, and the presence of an excess of sand is necessary. The loss of lead and silver by volatilisation in such ores is less, however, probably, from the rapid formation of sulphuric acid by the oxidation of the pyrites, and the conversion of the lead and silver into sulphates.

When the roasting is complete, the only reducing agent necessary in the blast-furnace is coke, the action of which has been previously explained.

The arsenical pyrites is always injurious; the formation of arsenious acid during the roasting, increases the volatilisation of the silver, but the greater part of the arsenic remains behind in the form of arsenates. In the blast-furnace, some more arsenic is volatilised in the upper zone, and part remains combined with the lead and in the matt in the form of arsenuret of iron.

Sulphide of antimony.—During the roasting, the volatility of the antimony increases the loss of lead and silver, and towards the end of this operation, it is impossible to decompose the antimonates, even with an excess of gangues and fusible silicates.

In the blast-furnace, the antimonates are gradually reduced by the gases, the iron, and the solid fuel, with the same facility as the compounds of lead. A part of the antimony is volatilised, by which the loss of lead and silver is increased, and another portion passes into the lead and matt. The presence of this substance necessitates the use of an increased proportion of iron and coke. The antimony also accompanies the lead in all the subsequent operations, although the greater portion can be removed in the calcining process.

Copper pyrites.—In the blast-furnace, the copper is nearly all reduced at the same time as the lead, and when a matt is formed, a portion of the copper is always present. The lead, however, always carries away some copper, which reappears in all the subsequent operations, after giving a characteristic appearance both to lead and litharge.

Blende.—During the roasting, the blende is more rapidly oxidised than the galena, being converted into oxide and sulphate of zinc, which is decomposed with difficulty in the second period, while the infusibility of the oxide impedes the melting of the other materials. It is, therefore, necessary to add some argillaceous compounds to such galenas, and prolong the roasting process. These compounds of zinc are not volatile, but, being infusible, are more liable to be carried off with the current of fume, of which they always form a large proportion; these fumes are richer in silver than those formed in treating similar galenas free from blende. It is not known in what state of chemical combination the silver exists in fume, but from the facts observed in treating ores with different gangues, it would appear that the presence of silver in the fumes is due more to mechanical than to chemical causes.

In the upper zone of the blast-furnace, the oxide of zinc is partially reduced, and as

Digitized by Google

the metal descends, it is volatilised, when it acquires a dark red heat, and burns at t mouth of the furnace, spreading its oxide on all sides. This metal has therefore beneficial action on the reduction of the lead.

In the lower zone, the oxide of zinc combines with the silica and retards the fusi while the iron does not easily reduce it, and the metal, once formed, is volatilis without any appreciable action on the silicates with which it comes in contact.

The slags contain some oxide of zinc, which render them of a refractory charact The lead produced, does not contain much zinc, as the temperature is too high to fav the combination of the two metals.

When the roasting has been imperfect, the sulphide of zinc is partially oxidised the aqueous vapour in the upper zone of the furnace, but the greater portion unites w the sulphide of lead, and forms matt. The greater porosity of these roasted materi from the presence of the infusible zinc-compounds, increases the reducing action of gases in the upper zone, and this again adds to the quantity of matt which is form This zinc-matt is, however, not so fusible as the others, and consequently rema longer in contact with the silicate of lead, on which it exerts a reducing action, only benefit derived from the presence of blende.

The volatility of the zinc increases the loss of lead and silver in various ways, by direct action, as well as by its rendering the roasted materials more porous, in con quence of the infusibility of its compounds in all the operations of roasting, smelti and treatment of the fume.

The great object therefore in treating such ores is to diminish the chances of vol lisation, by perfect roasting, and the addition of fusible slags in sufficient quantity overcome the infusibility of the zinc compounds. The beneficial action of iron pyri in such ores, is due to the facility with which it melts, thus counteracting the oppos tendency of the blende; but the quantity necessary to accomplish this effect may the percentage of blende is great, prove so large as to render the ore too poor for a kind of metallurgical treatment.

II. The Refining of the Lead.

All lead ores contain more or less silver, and as the latter metal is reduced alo with the lead, its separation becomes an object of commercial importance. The cost separating silver by the old plan of cupellation, renders it impossible to refine le with less than eight ounces of silver per ton, and the world is indebted to the late M Pattinson for the discovery of a beautiful process, by which lead with no more th ½ oz. will now pay for its extraction.

The separation of silver, therefore, now involves three operations, viz. desilveri tion, cupellation, and the reduction of the pot-dross and litharge.

1. Desilverisation.—Pattinson's *Process.*

This process, known among the workmen as the *separating* process, and called France, *Pattinsonage*, consists in slowly cooling the melted lead in iron pots, duri which a portion of the contents assume a crystalline form, and sink to the botto These crystals contain less silver than the portion which remains in a liquid state.

The composition of this desilverised lead, from different localities, is given in t table below.

The pots are large metal pans, and are generally set in a row of 10 or more, those the left being called the *working* pots, and that to the right, which is smalle the *market* pot, from the circumstance, that the *poor* lead is ladled from it into t pig moulds, ready for market.

The mode of setting a range of these pots is so clearly shown in *fig.* 611, as supersede the necessity of any description.

Digitized by Google

Fig. 611.

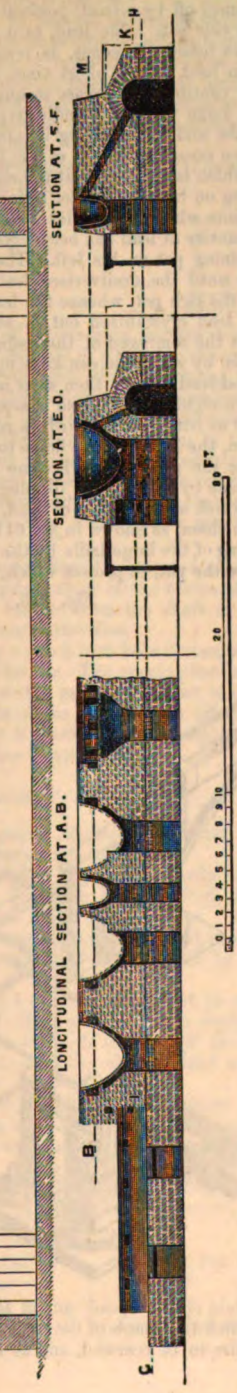

Fig. 612.

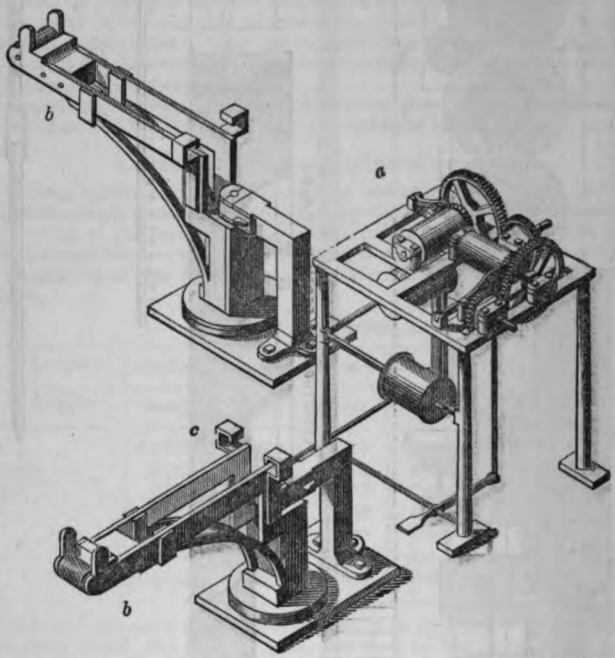
Digitized by Google



The operation is conducted in the following manner:—One of the pots about middle of the range is filled with pigs of lead, which are melted. The dross which fo on the surface is skimmed off by a small perforated ladle, when the fire is withdr from the grates below this pot. The lead, as it cools, is constantly stirred, and portion which solidifies round the edges, is removed by an iron paddle or *slice*, mixed with the molten lead. In a short time, the crystals, above mentioned, m their appearance, and continue to increase in quantity as the cooling progresses. workman then dips a large perforated ladle, represented in *fig.* 612, into the mas liquid lead and crystals, and withdrawing it, allows the liquid portion to drain aw which he hastens by an occasional shake of the ladle. He then attaches to the sh of the ladle, a hook, which is suspended at the end of a chain hanging upon the jo of the roof, and holding on by the handle, swings the ladle full of crystals over next pot to his right, into which he empties the crystals. He continues this operat until the necessary quantity of lead has been crystallised out, when the liquid port is ladled into the adjoining pot on his left. The same operation is repeated with the intermediate pots, until the desilverised lead arrives at the market-pot, and enriched lead reaches the rich pot, whence the lead is taken for cupellation.

The proportion of lead crystallised out in each pot varies very much with richness of the lead at the command of the refiner, and especially if he has *origi* leads of different values, by which he can keep up a continuous supply of lead to e pot. When the original lead is poor, then what is known as the *low system*, is adopt where as much as seven-eighths of the lead is separated; but with richer lead, the *h system* is followed, and as little as two-thirds is removed as crystallised lead.

During the operation, the large ladle is liable to cool by its repeated exposure to air, and in consequence the perforations become closed by the adhesion of the le This difficulty is overcome by occasionally dipping the ladle into the small intermedi pots on the one side, which are kept full of lead, maintained at a higher temperat by a small fire beneath them, as shown in *fig.* 611.

The shaking or jerking of the large ladle by the workmen when draining the cryst would ultimately injure the pot, to protect which, a pig of lead with a bar of iron c

Fig. 613.

in its upper surface, is laid on the broad rim of the pot, and this serves at the sa time as a fulcrum on which the shank of the ladle rests.

These pots often require to be renewed, and as a large weight of metal in the ri

Digitized by Google

is rendered useless in each renewal, the upper portion of the brickwork is covered in some works with a circular metal slab, on which the narrow rim of the pot rests, by which a saving of expense in the repairs is effected.

This process is also accompanied by another advantage in purifying the lead. Each time the lead is melted, the surface becomes covered with a scum, which contains more or less impurity along with the oxide of lead, and this dross being always skimmed off, the quality of the lead is continuously improved as it approaches the market-pot. This circumstance is so well recognised, that leads containing only one ounce silver per ton, and even less, are regularly treated by this process, especially when the lead is to be used in the manufacture of white lead.

An average cost, founded on the crystallisation of 1,917 tons of lead containing 24 ounces of silver per ton, was found to be as follows:

	s.	*d*
Labour	9	7·6
Coals, 6·2 cwt.	1	0·4
Repairs	0	2·9
	10	10·9

Stagg's apparatus.—The expense of labour is an important item in Pattinson's process, and none but powerful men are capable of managing the crystallising ladle. This objection attracted the attention of the late Mr. I. D. Stagg, who succeeded in constructing an apparatus for obviating this difficulty. This arrangement, known as *Stagg's apparatus*, is represented in *fig.* 613; it consists of a crane and windlass, *a b*; a chain attached to the end of the shank of the ladle is wound up by the windlass, and draws up the ladle, filled with crystals, out of the pot. A workman guides the handle of the ladle, which is afterwards placed under a catch, *c*, of the crane. While the crystals are draining, the ladle is occasionally shaken by the workmen, and by moving the crane, the ladle is easily carried over the adjoining pot, into which the crystals are emptied.

Worsley's apparatus.—This gentleman has also patented arrangements by which the labour is economised. He fixes an upright shaft in the centre of the pans, with a bearing at top and bottom, while arms radiate from the shaft to the sides of the pans; with this apparatus he obviates the use of the slice.

The other plan consists in drilling a ¼ to ½ inch hole horizontally through the side of the pan, about two inches above the bottom. The opening inside the pan is covered with a sheet-iron strainer screwed down to the pan, and a spout is set in an opening made through the side wall of the fire-hole of the pan, to carry off the liquid lead into a pot placed outside. The hole in the pan is made tight by a slightly tapering *tapping bar*. The crystals remain behind for further treatment.

Parkes' *Process.*

This process depends upon the superior attraction of silver for zinc over lead, and is applied by Mr. Parkes in the following manner:

The silver-lead is melted in one of the large pans already described, and raised to the temperature of melted zinc. The zinc being melted, is then added, and the fluid metals are stirred for a period of one to two hours. The fire is now lowered and the metals allowed to cool down until the lead is about to set. The zinc and silver rise to the surface during the interval, and are removed by means of a perforated ladle.

This alloy is afterwards heated in a sloping iron retort to remove a portion of the lead, which contains 1,000 ounces of silver per ton, and is ready for cupellation. The portion left in the retort, is heated in clay pots to distil off the zinc. The residue contains silver mixed with the impurities of the original lead and zinc. It is melted with lead and cupelled to obtain the silver.

Mr. Parkes also proposed to roast the alloy in close retorts or muffles, by which it was reduced to a fine powder, which was then to be treated with dilute sulphuric acid. The foreign oxides dissolved in the acid, leaving the silver, which was treated in the usual way.

The quantity of zinc required to desilverise the lead, depended upon the proportion of silver and other metals present in the lead, and he gave the following statement in his specification—viz. for 20 cwt. of lead containing

14 oz. of silver per ton . . .	22·4 lbs. of zinc.
21 „ „ „ . . .	33·6 „
28 „ „ „ . . .	44·8 „

The loss of lead in this process is said to be about 1 per cent., but on account of

Digitized by Google

the difficulty in treating the alloy of zinc and silver, Messrs. Neville are understood have abandoned the plan.

Separation of Copper in Crystallisation.

Mr. Baker has published the following results of an inquiry to ascertain how far t impurities of lead, viz. silver, copper and iron, are removed in this process of crystal sation.

The original lead contained:

	1	2
Silver . . .	0·0046	0·0052
Copper . . .	0·0066	0·0154
Iron . . .	0·0065	0·0068
Sulphur . . .	trace	trace.

The various products of the process contained:

	Silver.	Copper.	Iron.
Rich Pot:—			
Before crystallising . . .	0·0108	0·0344	0·0312
Crystals, 25 pts. . . .	0·0052	0·0152	0·0086
Fluid lead, 85 pts. . . .	0·0140	0·0476	0·0122
Second Pot:—			
Before crystallising . . .	0·0052	0·0154	0·0068
Crystals, 95 pts. . . .	0·0020	0·0066	0·0118
Fluid lead, 25 pts. . . .	0·0126	0·0286	0·0146
Third Pot:—			
Before crystallising . . .	0·0020	0·0102	0·0118
Crystals, 70 pts. . . .	0·0010	0·0038	0·0198
Fluid lead, 25 pts. . . .	0·0100	0·0240	0·0082
Fourth Pot:—			
Refined lead	0·0014	0·0054	0·0112

From this Mr. Baker very naturally draws the conclusion that there is an alloy copper-lead which remains fluid when crystals of lead are formed, and that when t former metal is present in moderate proportions, it may be separated from the lat by a process similar to that of Pattinson.

This statement has been disputed by Reich and Streng, who deduce from their e periments the conclusion, that the copper is not separated; but the writer, witho having analysed the different leads, inclines to believe in the correctness of Mr. Bake conclusions.

2. Cupellation or Refining of the Rich Lead.

Although it may be difficult to assign a correct interpretation to Hebrew terms art, yet we think it is clear that the use of lead in purifying other metals was kno in very ancient times. Jeremiah would seem to allude to this fact in the passage ch. vi. ver. 29, and similar reference is made in Ezekiel xxii. 18–22, Malachi iii. 2, The first notice of the process of cupellation among the ancients, appears in t works of Dioscorides; and Pliny and Geber describe an operation which is a tr cupellation by means of lead. In 1343, Philippe le Bel issued an ordinance prescri ing the use of cupels for testing the precious metals. In 1556, Agricola in his wor *De re Metallica*, fully describes the whole process, with instructions how to make t tests; this was followed by the work of Barba, *Arte de los Metales*, in 1640, where t construction of the refining furnaces is minutely explained.

The chief object is generally to separate the silver from the lead, but when an oxi of lead in the form of litharge is wanted, then the former becomes a secondary operatio

There are many modifications as to the form of furnace, mode of refining, &c., b only what may be called two distinct methods of cupellation—viz. the English a German.

The English System.

The peculiarities of this system consist in the cupel being movable, and the lea being fed at intervals.

The furnace, which is termed a *Refinery*, is represented in *figs.* 614, 615, where tw cupels can be worked at the same time when necessary; *a a* are the positions of th cupels or tests, one of which is shown resting on an iron waggon, *b*; *c c*, the pots contai ing the rich lead in a melted state, which is ladled into an iron gutter, *d d*, to suppl the test; *e e*, the point where the blast enters, and *f f* the opening or *gate*, through whic the litharge is blown over into a pot below; *g g*, the fire grates, and *h h* the ash pits *i i*, the flues, and *k k* the chimneys.

s apparatus is shown in *fig.* 617 in such detail as to . It is worked by hydraulic pressure.

Digitized by Google

The test is allowed to dry in the air for some time, and then placed on the waggon, which is run into position. The test is then wedged tight up against an iron ring built firmly in the masonry. The fire is now lighted and the test carefully annealed, otherwise it is liable to crack. When perfectly dry, it is heated to a dull redness, and then filled with the melted rich lead.

This lead soon becomes coated with a greyish dross, but as the heat increases, the surface of the lead appears, and the formation of litharge commences. The blast is now turned on, and while supplying the oxygen necessary for the oxidation of the lead, it drives the litharge to the mouth of the refinery, where it flows in a continuous stream over the gate into a little iron pot placed on wheels for the convenience of removal.

When there is only enough rich lead to yield a small cake of silver, the refining is completed in the same test, and in that case, the workman cuts down the opening in the bone-ash at this end of the test, which is called the gate, to the level of the melted lead, until the *fining* of the silver commences.

When there is a stock of rich lead, the concentration of the silver is confined to the first test, which is called the *lead-test*. As soon as the silver amounts to about 8 per cent. of the contents of the test, a small hole is carefully drilled in the bottom, and the rich alloy is run into moulds. The hole is then closed by a pellet of bone-ash, and another cupellation commenced. The rich alloy is afterwards refined in the same manner in another test, hence called the *silver-test*.

When the lead has been nearly all oxidised, the film of silver becomes thinner and thinner; it then exhibits a succession of the beautiful iridescent tints of Newton's rings, and at length the film of oxide disappears, revealing the brilliant surface of silver beneath. Such is Dr. Miller's admirable description of this beautiful phenomenon, known as the *fulguration* of the metal, or as the men call it, the *brightening of the plate*.

At this point the blast is turned off, the fire withdrawn, and the silver allowed to cool. When the silver has *set* and begun to harden, the wedges are removed, and the test with its cake of silver falls on the iron waggon. When cold, it is removed, the impurities adhering to its under surface are chipped off, and the silver is ready for fusing into ingots.

During the cupellation, the silver absorbs oxygen, which is evolved as the metal cools, forming crater-like eruptions on the surface, and the extent of these protuberances is a very good indication of the purity of the silver.

There is not much silver lost in the refinery by volatilisation, but a comparatively large absorption takes place in the test. We have assayed several test-bottoms, and have found the contents in silver to vary from 74 oz. to 115 oz. per ton of test.

Chambers' Steam Blast.—The blast employed in refining must be soft, and is best supplied by means of a fan, but a very excellent plan of Mr. Chambers was tried by the writer, and furnished very good results. It consisted in substituting a steam jet for the blast of air, and as the steam passed through a wide nozzle, it carried sufficient air along with it to oxidise the lead, while mixing a body of steam with the lead fume, which was thus more completely recovered in the long flues by the condensation of the steam.

A more simple and compact form of refinery is shown in *figs.* 618, 619, where the steam blast-pipe is represented entering the furnace at *a*. This refinery is also fitted with an iron hood, *b*, placed in front of the working door, where occasional puffs of fume are blown over the workman. This fume is carried off by an iron pipe, *c*, into the chimney, and this protects the men from the injurious consequences of inhaling the lead smoke.

The following statement as to the cost of refining, is founded on the cupellation of rich lead, which produced upwards of 60,000 oz. of fine silver:

							s.	d.
Labour							3	10·3
Coals	4·7 cwt.						0	9·4
Pearl-ashes	0·6 lbs.						0	4·0
Bone-ashes	18·7 „						3	3·8
Repairs							0	2·0
Engine Power:	Coals cwt.	5·2	=	0	10·4			
	Wages			1	0·3		= 1	10·7
						Per ton of lead	10	4·2

or 3*s.* 1·1*d.* per 100 oz. of silver.

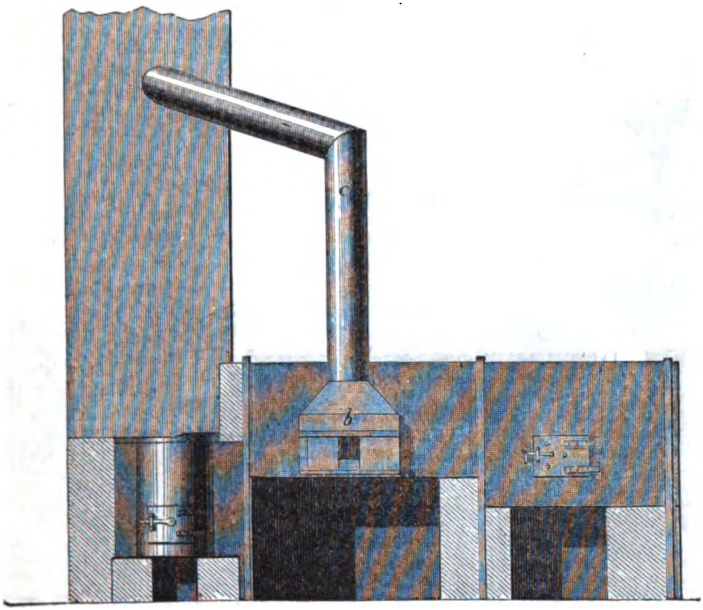
When the silver has been removed, the test is broken up, those portions of the bone-ash which are free from lead, being removed for subsequent use, and the rest is generally

Digitized by Google

carried to the slag-hearth or blast-furnace, where the bone-ash of course is lost. Mr. Johnson recovers this bone-ash as follows:—

Johnson's Process.—He reduces the cupel to a powder, and mixes it with acetic acid of 1·030 to 1·048 specific gravity, in sufficient quantity to render the mixture of a thin

Fig. 618.



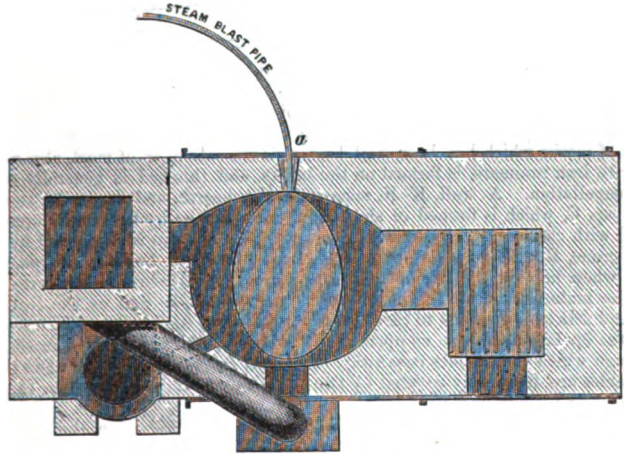


Fig. 619.

consistence to admit of its being well agitated in a dolly tub. The greater part of the lead dissolves, and by renewing the acid, a further quantity is removed, so that, on working the residue to separate all the solution, the bone-ash is sufficiently pure to be employed again in making tests. The solutions yield the lead, in the form of sugar of lead, by concentration.

The German System

differs from the English in forming the hearth of marl instead of bone-ash, making it of large dimensions, and charging all the lead at one time.

The form and construction of this furnace is shown in *fig.* 620, which is tak an excellent treatise on the Metallurgy of Lead by Dr. Lamborn. The corne

Fig. 620.

right is removed, to show the interior. The circular portion contains the heart rectangular fireplace. The foundations, F F, are built of stone, cramped with ir and pierced with openings to carry off the moisture. A, represents the firep which either wood or coal can be burnt. The hearth is formed of bricks set on a bed of scoriæ which has been well beaten down. A layer of marl, also c beaten with iron rammers, is formed on the bricks, and this bed is generally r at each cupellation. A wall, K K, surrounds the hearth, and serves to su movable cap, C, which is formed of sheet iron, strengthened by bars on its upp and lined with clay secured by numerous iron straps. The cap is suspended by from the crane, R, and supported by a lever, L, so that it can be raised or rem one side, when necessary. The opening, G, opposite the fire-bridge, B, serves troduce the materials of which the hearth is constructed, as well as the lea refined, and acts as a chimney to carry off the products of combustion. The w watches the operation through an opening in the corner, which is removed in th cut, through which the vapours pass away. The blast enters at T, through two t whose nozzles are frequently covered by two small valves, called *butterflies*, to the blast over all the surface of the bath.

When all is ready for work, a thin bed of straw is laid upon the hea which the pigs of rich lead are piled. The cap, C, is then lowered on the walls, an with clay all round the edges. The fire is then lighted, and soon after the melted, its surface is covered with a dark crust called *abzugs*, consisting of the ox the foreign metals, and other impurities from the lead. This crust is drawn off t the working door, opposite T. The fire is kept up to maintain the lead at a da heat, while the impurities, termed *abstrichs*, continue to separate. The table follows, contains the analysis of some of these products. The next product appears, is known under the name of *cupreous* or *wild Litharge*, and at the end hours, the formation of the true litharge commences. The heat is now mai between a cherry and a bright red, until the operation is complete.

The progress of the cupellation is carefully watched, and samples of bot litharge and the metal on the test are analysed from time to time. The mixed are dissolved in nitric acid, and an excess of hydrochloric acid is added to conve metals into chlorides. Strong alcohol is added, which precipitates the chlori silver and lead, and the bismuth is thrown down from the solution by carbon ammonia, then filtered, and weighed.

Manufacture of Litharge.

An oxide of lead is in demand for the preparation of acetate of lead and purposes, and this substance is produced in two forms, as *Flake* and *Lev* litharge.

Flake Litharge.—When litharge is manufactured for sale, the purest lead, n in silver, is selected for cupellation. The refining process is conducted as a described, but the oxide of lead at the commencement and termination of the cu tion is rejected.

The litharge, as it flows from the test, is received in large pots fitted on whe which it is allowed slowly to cool. In some cases, the pots are heated so th cooling may be more gradual, as the proportion of the flake litharge depends upo condition. When the pots are emptied, the mass of litharge falls, and the wh passed through a circular temse, working in a close wooden erection to protect th from the dust. The fine flake litharge is collected and packed in casks.

Levigated Litharge.—The portion of litharge which does not fall, but remains i fused pieces, is employed for the manufacture of levigated litharge.

The process consists in simply grinding this fused litharge between horizontal with a supply of water. The mill employed for the purpose is seen in *figs.* 621

quantity of coal, on which a mixture of the oxides

Digitized by Google

and coal is thrown near to the fire-bridge. The ignition of the fuel and the reduc gases in the furnace soon causes a reduction of the metallic oxides, and the liq metal trickling down through the porous mass, finds its way to the point, F, whenc flows into the metal pot, G. The charge is frequently turned over by an iron rak present fresh surface to the reducing action of the fuel, and to facilitate the escap the lead. Fresh charges are introduced during the shift, and at the close of the the residual matters, termed *cinders*, are raked out.

In smelting works, there ought to be at least three of these reducing furnaces which the oxidised products of the different operations can be reduced, viz., one for drosses, another for litharges, and a third for calciner's dross, to be described in next section. This necessity arises from the difference in the quality of the lead duced, and which, by being mixed, would afterwards entail an unnecessary expens

The dross is reduced in precisely the same way as the litharge, but when it is impure, the addition of a little soda-ash facilitates the operation and increases the duce of metal. The dross from the poor pans must also be kept distinct from tha the rich pans, as the difference in the contents of silver saves some expense in the sequent desilverisation of the two leads.

The same remark applies to the litharge, especially that which flows off towards conclusion of the cupellation.

The cost of reducing litharge and pot-dross is nearly the same, and the follow details may be taken as an average:

III. Softening of hard Lead.

All the lead produced at the blast-furnaces, and some leads obtained from poor in the reverberatory furnaces, are so hard from the presence of impurities or other ca as to render them unfit for treatment in the desilverising process. The lead obta from the English slag-hearth (p. 520) is also of the same character, and, until wi about the last twenty years, was sold for running lead-joints, &c., irrespective of contents in silver. The composition of some of these hard leads is given in the fol ing table:

The writer having carefully examined the W B slag-lead, found that its hardness mainly due to the presence of antimony. He then suggested the erection of furnac which this lead, in a melted state, could be exposed to a current of hot air. The result the production of a good soft lead, at so reasonable a cost as to render the pro available as a regular operation in smelt mills.

Soon afterwards, the first cargoes of the now well-known Spanish hard lead arrive Liverpool; but the smelters there would not purchase them, and one cargo was t shipped to Newcastle-on-Tyne. This lead could not be softened in the brick furna being so fluid when melted, as to find its way out of the furnace in all directions. late Mr. G. Burnett, who consulted the writer on the subject, and witnessed the treatm of the slag-lead at Mr. Beaumont's works at Blaydon, then proposed the simple admirable plan of lining the furnace with a metal pan. Thus was laid the founda of a trade with Spain, which has gone on increasing, until, it is said, upwards of 20, tons of this description of lead are annually produced in that country.

Calcination of the Lead.

The furnace generally employed in this operation, termed *calcining* or *improvin* the workpeople, is represented in the *figs.* 625, 626 in elevation and vertical sect A is the fireplace; B, ash-pit; C, fire-bridge; D, cast-iron pan; E, flue; F

examined when cold, and if it is soft to the scratch, with a flaky, crystalline appear on the surface, the contents of the pan are ready to be run off through the iron s into a pot on wheels, whence it is ladled into pig moulds.

An improvement has been made on the above simple form of furnace, which is sh in *figs.* 627, 628, representing a front view and a longitudinal section. The hard le melted in the pot, *a*, which is heated by the fire, *b*. The calcining pan, *c*, is sup with melted lead from the pot by raising the plug, *d*. The soft lead is run into pot, *e*, and then cast into pigs. This form of furnace possesses great advantages softening extra-hard lead, as the calcining pan can easily be kept always full, very little labour.

The produce of soft lead from the hard leads, of course, varies greatly, as will be from the following table, which contains the results of the treatment of many hund of tons of most of the descriptions named:

Good Spanish hard lead	93·2	per cent. soft lead.
Hard lead from crystallising dross . .	90·3	„ „
Hard lead from economic furnaces . .	84·3	„ „
English slag lead	87·1	„ „
Slag lead from Spanish dross . . .	66·9	„ „
Slag lead from refuse products . . .	67·3	„ „
Tea lead	76·4	„ „

We have mentioned tea lead as among the hard leads which can be treated by process, and we have found that tin is as easily separated thereby as antimony.

The following hard leads were mixed and submitted to calcination:

Pontifex and Glassford's Process.—These gentlemen employ the ordinary calc pan-furnace, and when the charge has been in operation for a few hours, the dross removed as usual, a few pounds of the following mixture is spread evenly ove surface of the bright lead. The doors are closed, and in about 10 to 20 minu brown or yellowish-brown cake collects on the surface. Fresh fuel is then throw the fire, and in a few minutes, when the smoke has cleared away, the doors are op and the cake is removed. This is repeated until the cake formed possesses a brig brown colour. When the alkaline mixture is used, with a charge of 9 or 10 to lead, about 55 lbs. are required during the 24 hours' operation. When the other ture is employed under the same circumstances, the quantity required varies bet 40 and 60 lbs.

The mixtures recommended are as follows:

1. For lead containing from 3 to 15 per cent. of antimony, the mixture consists

3 parts of nitrate of soda.
4 „ soda-ash.
4 „ burnt lime.

2. For lead containing 2 to 3 per cent. of antimony, and from ½ to 1½ per cen silica, the mixture consists of equal parts of soda-ash and caustic lime.

We understand that this process has been discontinued, and if it be true that antimony exists in the hard lead in the form of an alloy of antimony and lead, w when the whole is melted, rises to the surface in consequence of its lower specific gra we cannot see how the time of softening should be shortened with advantage, at the cost of so expensive an oxidising agent as nitrate of soda. In the old mode of work

Digitized by Google

when the surface of the lead is kept constantly clear of dross by the calciner, the alloy, as it rises, is immediately oxidised by the current of hot air, whereas in this process, a considerable time is lost in allowing the mixture to act, and before the crusts are removed.

Mr. Barker of Sheffield has, however, succeeded in using the nitrate of soda and bisulphate of soda to advantage in this process, possibly from the fact that the impurities in his lead are so much smaller than in those of Spain, and by performing the operation, it is said, in crucibles.

Reduction of the Dross.

This process is performed in an ordinary reducing furnace, of smaller dimensions than usual, as the charges are smaller and require more attention to prevent the loss of antimony by volatilisation. The writer also introduced the use of a little soda-ash with the coal, when mixed with the dross, which was found to render the slag which is formed, more fusible, and enabled the workman to work at a lower heat. The following analyses of the hard lead obtained from this dross, with and without the addition of this flux, prove the advantage of its employment:

	Without the soda-ash.	With 2½ per cent. of soda-ash.
Lead	82·88	58·70
Antimony	16·09	40·66
Copper	0·68	0·32
Iron	0·35	0·32
	100·00	100·00

With the use of this flux, and continuing the calcining operation on the produce of the reducing furnace, the metals obtained were found to possess the following composition, according to the analyses of the writer:

English Hard Lead.

	Original lead.	1st calcination.	2nd calcination.
Lead	99·27	86·53	52·84
Antimony	0·57	11·29	47·16
Copper	0·12	traces	traces
Iron	0·04	0·34	traces
	100·00	98·16	100·00

Spanish Hard Lead.

	Original lead.	1st calcination.	2nd calcination.
Lead	95·81	64·98	56·60
Antimony	3·66	29·84	43·40
Copper	0·32	5·90	traces
Iron	0·21	0·20	traces
	100·00	100·92	100·00

It was found impossible to separate any soft lead from the product of the second calcination, all the metal becoming oxidised. This alloy is found of great use in casting type furniture, and in making some of the coarser kinds of type.

The cost of reducing the dross, per ton of lead produced, is as follows:

	s.	*d.*
Labour	5	2·1
Coals, 7·6 cwt.	1	3·2
Soda-ash, 34 lbs.	2	1·5
Repairs	—	
	8	6·8

Separation of the Antimony.

Instead of reducing the dross which yields the lead of the second calcination, the writer proposed to grind it to powder, and treat it with acetic acid, by which all the lead is dissolved, and yields sugar of lead by evaporation and crystallisation. The insoluble residuum, when reduced in the usual method employed for antimony ores, furnishes this metal very readily, and of fair quality.

The same process is applicable to the separation of the oxide of tin when the dross has been formed by treating tea lead.

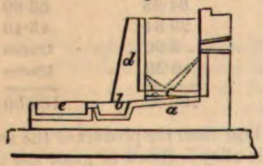
IV. Smelting of the Slags and other Products.

All the waste products resulting from all the previous operations—viz. ore o slags from the reverberatory furnace and ore-hearths, test-bottoms, litharge and cinders from the reducing furnaces, &c., are finally submitted to a process duction, in this country in a furnace known as the slag hearth, but abroad th generally mixed with poor lead-ores, and smelted in a blast furnace. We will de the method adopted in this country, and then select one of the continental plans illustration of the other method.

1. *The English Slag Hearth*

is known among the Germans as the *Krummofen*, or crooked furnace, and s the French as the *fourneau-à-manche*, or elbow-furnace. The general form construction of this furnace are shown in *figs.* 629, 630, &c. It somewhat resembl ore-hearth.

Fig. 629.



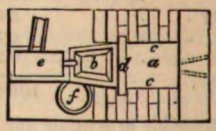


Fig. 630.

Hearth.—The sole-plate, *a*, is made of cast iron, and slopes slightly down to th hearth, *b*. There are strong cast-iron pieces, or *bearers*, *c c*, on each of the long s the sole-plate, which support the side walls as well as the cast-iron plate, or *forest* which forms the front of the shaft. The back is made of cast iron up to the hori tuyere in the middle, above which it is built of sandstone. A cistern, *e*, sta front of the fore-hearth, and a stream of water constantly flows through to gra the slag, and facilitate the subsequent separation of any pieces of lead dissem through it by washing. The lead flows over the fore-hearth into an iron pot, *f*, from below by a fire.

The bottom of the furnace is filled with small cinders, beaten down, and reach within 4 or 5 inches of the tuyere. The pot is also filled with similar cinders, filter the lead from the fusible slags which sometimes accompany the metal. then piled up above the bed of cinders, ignited, and the blast turned on.

When the peat is ignited, some coke is thrown in, and a layer of grey slag or refuse lead product is added. This is continued at intervals as the operation pro alternate layers of slag and fuel being added, metallic lead being produced, and a slag, free or nearly free from lead. The smelter occasionally forces a bent ir through the layer of cinder, to liberate the slag, which flows off into the water c

The fuel employed is coke, and during the smelting, part of the iron of the matt combines with the silica of the slags and cinders, forming a new, very fusible slag. Another portion of the iron reduces the sulphide of lead, producing metallic lead and a second matt.

The following table contains the analyses of some slags made in smelting cupel bottoms, &c.:

This matt is treated in the same manner as before, but in the fourth matt the copper has accumulated to such extent, that it is called the *copper matt*, and is treated for that metal.

This accumulation of copper is always observed, however small the percentage of copper in the original ore. The copper, having a stronger affinity for sulphur than lead, goes on accumulating in these matts, and generally pays for its extraction.

The mixture smelted in these Clausthal furnaces, consists of:

34 parts of ore containing 24 of galena.
4 to 5 „ cupel bottoms.
1 „ the abstrichs from the refinery.
39 „ ore slags.
4½ „ granulated cast iron.

which mixture is stated, by Regnault, to produce 19 pts. of metal, and 7 or 8 pts. of the first matt, containing 2½ pts. of metal.

V. Condensation of the Lead Fume.

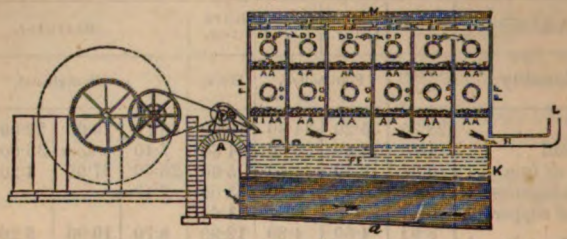
Since attention has been drawn to the great loss of lead in smelting its ores, numerous plans have been proposed to recover a portion of the metal in the form of fume, no fewer than sixteen patents having been enrolled for this object.

Where sufficient space exists, the plan most generally adopted is that of long flues and chambers. In some cases these flues extend for 5 miles. In Mr. Beaumont's extensive works, his able engineer, Mr. Sopwith, added nearly 5 miles of flue to one mill, the flue being 8 ft. high by 6 ft. wide. The saving in lead in these flues of Mr. Beaumont, is said to exceed £10,000 per annum.

Of the many plans which have been suggested, we will select two which are in successful operation.

1. *Stokoe's Condenser.*

This apparatus is represented in *fig.* 635, and has been found to answer remarkably well at Langley mill, as the details of an experiment, given on p. 525 amply prove.



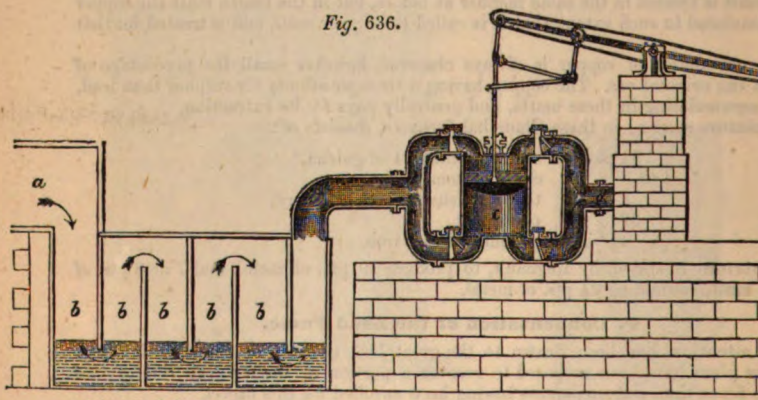
A is the top of the fume-flue; B is a wheel fixed in a metal case, set in motion by steam or water power, with a speed of 10,400 revolutions per minute, by which the fume is withdrawn from the flue and forced through the condenser. This condenser is rectangular, divided longitudinally by wooden rails, A, A, laid horizontally, on which a layer of pebble-stones, or other filtering material, is placed. The condenser is further separated into compartments, D. D, by the vertical divisions, C, C, which alternately reach the top, and dip below the surface of the water. The water flows from an open trough, M, divided crossways, immediately above D D, into the compartments, E, E, each of which is again subdivided by four or more low parallel partitions. The bottom

Digitized by Google

of these cisterns, E E, is perforated. The water is supplied by a pipe, D G, a bottom of the condenser is kept filled with water to the level shown at F F.

The fume is withdrawn from the flue, and forced up and down through the beds, in the direction of the arrows, until the residual gases escape at H, i chimney, L. These fumes, in their passage through the condenser, come in with the water from E E, which is constantly falling in fine showers over the

Fig. 635.



beds. The water carries down all the fume into the reservoir, F F, when occasionally drawn off at K.

The following table (p. 525) gives the results of an experiment, on the larg with one of these condensers.

Stagg's Condenser.

This apparatus is represented in *fig.* 636, in which *a* is the fume flue, *b b b b*, a constructed of wood or any other material, with partitions, dividing it alt

Fig. 636.

at top and bottom; *c*, one or more air-pumps, or exhausting machines; an exit-flue for the uncondensed gases. The air-pumps being set in motion, t is drawn through the water in the cistern, in which the metallic vapours densed, so perfectly, that the writer has walked along the exit-flue without bei with a single particle of fume. The passage of the vapours under the water c great agitation and spraying of the water, which materially assists in the co tion. When the water becomes charged with fume, it is drawn off by cocks, into tanks to allow the fume to subside.

Mr. Stagg has drawn up the following table from his experiments, to s annual saving of lead which may be effected by his condenser, and the vo gases for which the exhausting apparatus must be constructed:

LEAD, ALLOYS OF. Lead forms alloys with several metals by simple fusion, and many of these alloys are definite chemical compounds, which produce mechanical mixtures when fused with either of the constituents in excess. This latter fact has given rise to the metallurgical operation of eliquation.

1. With Antimony.—Lead alloys itself with this metal in several proportions, and the alloys are harder, more tender, and oxidise more easily than lead; they are also more fusible, as well as harder than either metal.

An alloy of equal parts of the two metals is porous and brittle: 2 pts. of antimony with 1 pt. of lead produce a very hard alloy, capable of receiving a fine polish, and used to make the keys of wind instruments; 3 pts., and even 4 pts. of antimony to 1 pt. of lead produce a hard but malleable alloy. An alloy of lead and antimony is used in making *type-metal*, a little zinc being sometimes added. Some type-founders add ¾ pt. of tin, but this addition is only suitable for stereotype plates. The plate on which music is printed is composed of 12 pts. tin, 7 lead, and 1 antimony. The ordinary composition of type-metal is 83 pts. lead and 17 antimony.

Emery wheels and grinding tools for the lapidary are formed of an alloy of antimony and lead.

Mr. Jas. Nasmyth has suggested the use of lead as a substitute for all works of art hitherto executed in bronze or marble. He states that the addition of 5 per cent. of antimony gives it not only hardness, but greater capability to run into the most delicate parts of the work. An alloy of this description, analysed by Karsten, and corresponding with the formula Pb^9Sb, was found on the hearth of a smelting furnace at the Mulder Works: it contained 90·10 p.c. Pb, 6·48 Sb, 1·42 Zn, 1·50 Cd, 0·24 Ag, and traces of Ni, As, and S.

2. With Arsenic.—The presence of this substance renders lead brittle, greyish white, and very fusible. The application of heat expels a portion of the arsenic, but the remainder resists the highest temperature.

This alloy constitutes the metal of which shot are cast, 40 lbs. of metallic arsenic being mixed with 20 cwt. of lead. It also exists native at Clausthal in the Hartz, and is composed of 67·63 p.c. Pb, 24·19 As, 4·41 mispickel FeAsS, 2·26 Fe, 0·54 S, and 0·7 Co.

3. With Bismuth.—This metal unites with lead in all proportions, with condensation. Some of the alloys are more malleable than lead, but the malleability diminishes as soon as the quantity of bismuth equals that of the lead.

When 3 at. lead are united to 2 at. bismuth, the mixture has only one solidifying point, viz. 129° C., but in PbBi, this point is 146°; in $PbBi^2$ it is 143°, and with Pb^2Bi^2 the temperature is between 163° and 171°.

These alloys have no special application in the arts, but they are used to adulterate mercury. An alloy of 1 pt. lead, 1 pt. bismuth, and 3 pts. mercury, is really an amalgam, which is sufficiently fluid to pass through chamois leather.

An amalgam of 2 pts. bismuth, 4 pts. lead, and 1 pt. mercury, is solid in the cold, but when pieces of it are rubbed together, they immediately melt.

Lead and bismuth occur associated in nature, in the mineral *Kobellite*, already described (p. 448).

4. With Bismuth and Antimony.—When antimony is added to the previous alloy in quantity equal to the bismuth, a metal is obtained which expands on cooling. Advantage is taken of this in casting stereotype plates. This alloy, according to Mackenzie, contains 70 p.c. lead, 15 antimony, and 15 bismuth.

5. With Chromium.—The alloy which contains 0·25 of chromium is fusible at 150° C., ashy-grey, but whiter than lead. It can be hammered into thin sheets, which are very brittle. Nitric acid dissolves the lead without attacking the chromium.

6. With Copper.—The alloys of lead and copper are difficult to prepare and to preserve at a high temperature. The copper must be introduced into a bath of lead heated above redness, and the alloy rapidly cooled; even then some portions are reddish-coloured, indicating the commencement of a disunion of the elements. If the alloy is heated to the melting point of lead, the latter abandons the copper, which is left in the form of a porous mass.

The process of eliquation is founded upon this fact, and as the silver present in the copper has a great affinity for the lead, the latter carries off the silver, which is separated in the manner already described (ii. 32).

In smelting sulphide of copper containing sulphide of lead, the latter metal passes off in great measure in the scoriæ in the first operations, but is found in the copper of the subsequent treatment.

Digitized by Google

There would appear to be two alloys of these metals, one containing m and melting at a higher point than the other, which contains more lead.

Small quantities of lead diminish the ductility of copper at ordinary te and at a red heat. Copper containing even 0·1 per cent. of lead, may still ordinary purposes, but it cannot be formed into thin sheets or wire.

The alloy of 4 pts. of lead to 1 pt. of copper is employed for casting lar types.

7. With Manganese.—When a mixture of 892 pts. of protoxide of ma 2789 pts. of litharge are heated with a little charcoal in a charcoal-line homogeneous, compact, and ductile alloy is obtained, which can be rolle sheets of great lustre.

8. With Mercury.—This metal is easily alloyed with lead, either by the former into the latter in a melted state, or by triturating lead filin mercury.

The amalgam possesses a brilliant white colour, and still remains with as much as 33 per cent. of lead, but it soils the fingers. The amalg parts can be crystallised, and a piece of lead plunged into this amalg covered with crystals when it is withdrawn.

The amalgam has a higher specific gravity than either of the metals, c contraction which they undergo in combining.

The presence of 0·0002 to 0·00025 of lead improves the mercury for use ters and thermometers, as the latter metal has then not so great a tende globules on the convex surface of the glass.

9. With Mercury and Antimony.—Wetterstedt has found that the a small quantity of mercury to the alloy of antimony and lead removes t of this metal to oxidation. He has proposed to use the triple alloy as a s ships. It is composed of 94·4 per cent. lead, 4·3 antimony, and 1·3 mer said not to be so rapidly encrusted with barnacles, &c. as copper sheath

10. With Potassium and Sodium.—The alloys of lead with these formed when a reducing alkaline flux is fused with oxide of lead, as first Vauquelin; and Serullas has described the properties of one of these allo when 100 pts. of litharge are strongly heated with 60 pts. of cream of t alloys can also be prepared directly; that containing 25 per cent. of it potassium is brittle, with a coarse-grained fracture. A similar alloy wit bluish and malleable, but that with one-third of sodium is brittle. T distilled with the iodides of ethyl, methyl, &c., yield the lead-compounds of radicles. (See LEAD-RADICLES, ORGANIC, p. 560.)

11. With Tin.—Lead may be fused with this metal in all proportions, but of the resulting mixtures does not correspond with the specific gravities metals. The following table contains the results of Kupffer's experiment

Composition of the Alloys.	Specific Gravity.			M P
	Found.	Calculated.	Difference.

The lead, so soft in itself, has the singular property of increasing the the tin: it slightly darkens the colour, gives a grained fracture, and caus liar creaking sound, produced on bending tin, to disappear.

The alloys of lead and tin are distinguished by the facility with which and burn. The alloy of 4 or 5 pts. of lead and 1 pt. tin burns like charc heat, the combustion continuing like that of an inferior peat, with the f

* Sn = 118 : Ppb = 207.

Digitized by Google

cauliflower excrescences. This action appears to be due to the affinity which exists between the two oxides. The oxides so formed, when fused either alone or with silica and an alkali, produce a white opaque *enamel* used for *dial-plates*, &c., and also in earthenware.

The *solders* used by plumbers vary much in composition, but there are three commonly known as *fine solder*, composed of 2 pts. of tin and 1 pt. of lead; *common solder*, containing equal pts. of each metal; and *coarse solder*, composed of 2 pts. of lead to 1 pt. of tin. Tomlinson gives the following table of the composition of these alloys and their melting points:—

	Tin.	Lead.	Melting Point.		Tin.	Lead.	Melting Point.
No. 1.	1	25	558°	No. 7.	1½	1	334°
„ 2.	1	10	541	„ 8.	2	1	340
„ 3.	1	5	511	„ 9.	3	1	356
„ 4.	1	3	482	„ 10.	4	1	365
„ 5.	1	2	441	„ 11.	5	1	378
„ 6.	1	1	370	„ 12.	6	1	381

No. 5 is also called plumber's *sealed solder*, which is assayed in the same way as pewter, and then stamped by the officer of the Plumbers' Company. No. 8 is used for soldering cast iron and steel, sal-ammoniac or common resin being used as flux. This alloy is also used for tinned iron, with chloride of zinc or resin as the flux. Gold and silver are also soldered with No. 8, and Venice turpentine for a flux. The same alloy is used with copper, brass, gilding metal, gun metal, &c., and sal-ammoniac, chloride of zinc, or resin as the flux; with zinc, and chloride of zinc as flux; with lead and tin pipes, with a mixture of sweet oil and resin as flux; with Britannia metal, and chloride of zinc or resin as flux. The alloys 4 to 8 are used for ordinary plumber's work, with tallow as flux.

Pewter is another alloy of these metals, and the trade in this article is so important in this country, that the pewterers have formed an incorporated company ever since 1474.

Common pewter is composed of 80 pts. of lead and 20 pts of tin, but other metals are sometimes added, such as copper, antimony, and zinc. The manufacturers of pewter state that a better pewter is obtained by working up old pewter with fresh ingredients.

Holtzapfel gives the following account of these alloys:—"Some pewters are now made as nearly as common as that of equal parts of the metals: when cast they are black, shining, and soft; when turned, dark and bluish. Other pewters only contain ⅛ or ¼ of lead; these, when cast, are white, without gloss, and hard; such are pronounced very good metal, and are but little darker than tin. The French legislature sanctions the employment of 18 per cent. of lead with 82 per cent. of tin, as quite harmless in vessels for wine and vinegar. The finest pewter, frequently called *tin and temper*, consists mostly of tin, with a very little copper, which makes it hard and somewhat sonorous, but the pewter becomes brown-coloured when the copper is in excess. The copper is melted, and twice its weight of tin is added to it, and from about ½ to 7lbs. of this alloy, or the *temper*, are added to every block of tin weighing from 360 to 390lbs. Antimony is said to harden tin, and to preserve a more silvery colour, but is little used in pewter. Zinc is employed to cleanse the metal, rather than as an ingredient. Some stir the fluid pewter with a thin strip, half zinc and half tin; others allow a small lump of zinc to float on the surface of the fluid metal, while they are casting, to lessen the oxidation."

Plate pewter is the hardest, and is used for making plates and dishes. The pewter called *trifle* is used for beer-pots, and *ley* for the larger wine measures.

Pewter wares are formed either by hammering or by casting, plates and dishes being hammered, while measures and spoons are cast. Pewter is also made in the form of sheets for engraving cheap music, the softness of the metal allowing the notes to be formed by means of punches, instead of engraving with a burin.

Lapidaries, jewellers, and watchmakers use laps and polishers of pewter.

Although lead is so poisonous a metal, it can be employed in domestic utensils, when alloyed with tin, which would appear to neutralise this action of the lead. In an alloy of 3 pts. of lead and 1 pt. of tin, Proust and other chemists have found that vinegar dissolves out nothing but the tin; but for domestic utensils, Vauquelin has shown that the lead ought not to exceed 17 or 18 per cent. An alloy of 3 pts. of lead and 5 pts. of tin is used for tinning certain articles of copper.

The *brilliants of Fahlun* are made with an alloy of 19 pts. of lead and 29 pts. of tin, which are fused together and allowed to cool for a short time. At this point the alloy adheres to a glass tube cut into facets, on which it is allowed to solidify, and

from which it can afterwards be easily removed. A lens plunged into this al
a brilliant mirror.

These alloys form superior baths in which to temper various articles of
following table contains all the information on the subject:—

Alloy.		Temperature.		Objects to be tempered.
Lead.	Tin.	C.	F.	
14	8	213·4°	415·4°	Lancets.
15	8	221	429·8	Other surgical instruments.
16	8	225	437	Razors.
17	8	240	464	Penknives, scalpels, cold-chisels.
28	8	257	494·6	Shears, gardeners' tools.
38	8	262	503·6	Hatchets, axes, planes, dressmakers'
60	8	275	527	Table-knives, large scissors.
96	8	284	543·2	Swords, watch-springs, &c.
100	8	289	552·2	Strong springs, poniards, augers, saws, &c.

For higher temperatures recourse must be had to other baths.

Alloys of lead and tin are also employed in making anatomical injections.

12. With Tin and Bismuth.—These ternary compounds are well kno
the name of *fusible alloys*. They melt at low temperatures, some even below
of boiling water. This is one cause why they are so rarely obtained in a
homogeneous condition.

There are several of these alloys known by the name of the first observer;
following all melt below the boiling point of water:

Observer.	Lead.	Bismuth.	Tin.	Melting po
Homberg. . .	1	1	1	122·00
Rose . . .	1	2	1	93·75
Newton . . .	5	8	3	94·44
Lichtenberg . .	2	5	3	
Krafft . . .	2	5	1	104·00

In whatever proportions the three metals are mixed, they exhibit one fixed s
point, at 98° C., and two higher points which are variable.

When 120 lbs. of an alloy, consisting of 3 pts. tin, 2 lead, and 5 bismuth, ar
they yield, on cooling, tolerably definite crystals, which melt below 100° C.,
tain nearly equal numbers of atoms of the three metals, or 15·76 per cent.
lead, and 57·68 bismuth.

The melting point of fusible metal is raised by the addition of potassium.

This alloy presents many anomalies in its dilatation and contraction; th
temperature from zero up to 35° C., the volume increases in the prop
100 : 100·83, and it diminishes up to 56° C. in the ratio of 100·83 : 99·13, wh
point of greatest density; it then begins to expand. It is remarkable
maximum volume, reached at 35° C. is the same as that which it possesses
which is the melting point of Rose's alloy.

It is impossible to determine the melting point of these alloys except by exp
thus, in Newton's fusible metal, which melts between 198° and 200° F., the th
point ought to be 520°, as shown by the calculation,

$$\frac{8\text{Bi} \times 500° + 5\text{Pb} \times 600 + 3\text{Sn} \times 442}{16} = 520° \text{F.}$$

The following table contains the melting points of various alloys of the
metals:

It is remarkable that the tin, which melts below the fusing points of both lead and bismuth, should raise the melting point of these alloys.

These alloys are of great value in regulating the tempering of delicate articles of cutlery. They are also used for taking impressions of medals, bas-reliefs, and on the Continent for producing casts of metals by the *clichè* process. They can also be employed to take casts from the surface of wood and embossed paper. Beautiful casts of the internal ear, showing the complexities of its bony cavities, have been made with them; also cake-moulds for the manufacture of toilet soaps.

Two of these alloys are well known in this country under the names of *Britannia metal* and *Queen's metal*. The former is composed of equal parts of brass, tin, antimony and bismuth; the latter of 1 part each of antimony, lead and bismuth, with 9 parts of tin. Both are used for making teapots, spoons, &c.

A safer and better alloy is said to be made by adding to 100 pts. of French pewter, 5 pts. antimony and 5 pts. brass, to harden it.

In Birmingham, teapots, milk-jugs, &c. are made into form by a process called *spinning*, which consists in bringing the sheet of pewter against a rapidly revolving tool, by which, with a little dexterity on the part of the workman, it is gradually fashioned.

13. With Tin, Mercury, and Bismuth.—The addition of mercury to the three metals forming the previous alloys renders them much more fusible, and communicates some new properties.

D'Arcet's alloy, similar to Newton's, when amalgamated with mercury, melts at 45° C. This alloy or amalgam is specially valuable in making anatomical preparations. It is introduced into the parts of the body in the liquid state, and allowed to solidify. The flesh and other animal matters are afterwards dissolved and removed by a strong solution of potash.

The interior of glass tubes, globes, &c. are tinned by means of this amalgam, which is poured into the vessel by means of a funnel, in the liquid state, and gently agitated. The surplus is then poured off, and the operation is complete. Glass of different colours is employed, and objects of great beauty are thus easily prepared.

The best compound is composed of 1 pt. lead, 1 tin, 2 bismuth, and 10 mercury. The first three are fused together, and then the mercury is added.

14. With Tin and Copper.—An alloy of these metals was used by the Romans for casting statues, &c. It was formed of 67·12 per cent. natural bronze, 22·37 old bronze, 5·25 tin, and 5·26 lead.

Bronze is made of copper and tin, to which some manufacturers add a little lead, and in the analyses of several ancient coins by Phillips, lead appears to have been an important constituent. (See Table, vol. ii. p. 45.)

When lead is mixed with copper in the proportion to 6 to 1, ordinary pot-metal is formed, called *dry pot-metal*, a quality which is characteristic of these alloys.

British bell-metal consists of 5·6 per cent. zinc, 10·1 tin, 4·3 lead, and 80·0 copper.

Biddery ware is made in India by combining 2 pts. of tin, 4 pts. lead, and 16 pts. copper, and is afterwards melted in the proportion of 3 pts. to 16 pts. of zinc.

The other alloys of copper to which small quantities of lead are added are described in another part of this dictionary.

15. With Zinc.—This metal communicates hardness to lead, and the property of receiving a fine polish, without diminishing the malleability. The two metals may be fused in any proportion, but the alloys are all decomposed at a white heat, the zinc being volatilised, and carrying off with it large quantities of the lead.

The presence of lead in zinc, however, is said to be injurious to the latter metal when rolled into sheets, diminishing its elasticity and probably its tenacity.

When equal quantities of *lead*, *zinc*, and *bismuth* are fused, an alloy is obtained which melts in boiling water.

LEAD, ANTIMONIDE OF. (See p. 532.)

LEAD, ARSENIDE OF. (See p. 532.)

LEAD, BROMIDE OF, $PbBr^2$, is obtained by the same processes as t which it resembles in crystalline form. It is somewhat less soluble in melts out of contact with air, at about the same temperature as the chloride horny mass. By fusion, in contact with the air, it is converted into a ba or oxybromide. It unites with the bromides of potassium and sodium, for talline double salts, which, however, are decomposed by water.

Acetobromide of lead, $Pb''Br^2.Pb''(C^2H^3O^2)^2$, or *Plumbobromacetin*,

is obtained like the corresponding chlorine-compound (p. 539), which it reser properties and reactions. (Carius.)

LEAD, BROMOCARBONATE OF. An insoluble compound, p boiling together equivalent quantities of bromide and carbonate of lead readily, and when further heated gives off carbonic anhydride, and leav bromide of lead.

A *bromophosphate* and *bromophosphite of lead* may be formed in like man

LEAD, CHLORIDE OF. $PbCl^2$, *Magisterium plumbi*, sometimes ca *lead*.—Lead unites but slowly with chlorine, the combination not bein with visible combustion; it is also but slowly attacked by hydrochloric only when in contact with the air; on the application of heat, it dissol with evolution of hydrogen. The chloride is prepared by boiling the pr carbonate, or sulphide of lead, with water, into which hydrochloric acid is drop as the resulting chloride of lead continues to dissolve, or by adding hydroc or chloride of sodium to a concentrated solution of a lead-salt. Chloride o also been found, as a natural product, called cotunnite, in the crater of after the eruption of 1822, mixed with chloride of sodium, and chl sulphate of copper. This native chloride occurs in trimetric crystals, $\infty P : \infty P = 99° 46'$; $oP : \breve{P}\infty = 149° 14'$; and the ratio of the prin brachydiagonal and macrodiagonal, is as 0·5953 : 1 : 1·1868. The obser are ∞P, $\infty\breve{P}\infty$, $\infty\dot{P}\infty$ $2\dot{P}\infty$, $\dot{P}\infty$. Also acicular crystals. It is soft enc scratched by the nail, and has a specific gravity of 5·238. Lustre adamanti ing to silky or pearly. Colour white. Streak white. (Dana, ii. 97.)

Chloride of lead dissolves in 135 pts. of cold water, in less than 30 pts. water, and separates from the solution in long, flat, needle-shaped crystal solves in pure water, and in strong *hydrochloric acid* more easily than in acid, and therefore separates from the acid solution on moderate dilution w and from the saturated aqueous solution, on addition of hydrochloric acid. somewhat soluble in weak alcohol, very sparingly in alcohol of 76 per cent soluble in alcohol of 94 per cent. Its solubility in water is greatly diminish presence of chloride of calcium. In solutions of alkaline hyposulphites, or of sodium, on the contrary, it is much more soluble than in water, so that, a solution of 190 pts. acetate of lead with 58·5 pts. chloride of sodium, onl pts. of lead-chloride are precipitated, whereas 139 pts. are formed. A solut chloride in strong hydrochloric acid is not precipitated by *sulphydric acid*, l dition of water, precipitation immediately takes place. A solution of lea mixed with aqueous sulphydric acid containing hydrochloric acid, forms a reddish-brown precipitate of sulphochloride of lead (p. 559). An aqueous s the chloride mixed with sal ammoniac is not precipitated by sulphuric acid.

Chloride of lead melts when heated out of contact with air, and may be though with difficulty; the fused mass solidifies on cooling, to a white t

* Atomic weight of zinc = 65; of tin = 118; of lead = 207.

Digitized by Google

fissured mass of specific gravity 5·8, formerly called **horn-lead**. When heated in contact with the air, it fumes strongly before the heat rises to redness, then turns yellow, and is converted into an oxychloride (p. 555). When it is heated in a stream of *carbonic oxide*, chloride of carbonyl (phosgene) $COCl^2$, is formed, and metallic lead is separated (Göbel). It quickly absorbs *ammonia-gas*. When it is moderately heated in *phosphoretted hydrogen gas*, hydrochloric acid is given off, phosphorus distils over, and metallic lead remains. A solution of *hypochlorous* acid converts it into peroxide of lead.

Acetochloride of lead, $Pb''Cl^2.Pb''(C^2H^3O^2)^2$, or *Plumbochloracetin*, $\begin{matrix} C^2H^3O \\ Pb'' \end{matrix}\Big\}\begin{matrix} O \\ Cl' \end{matrix}$ is obtained in monoclinic crystals, by mixing recently precipitated chloride of lead with acetate of lead, and a sufficient quantity of glacial acetic acid to form a viscid mass, which solidifies in a short time, and either freeing this mass from excess of acetic acid by pressure, or heating it in a sealed tube to 130° or 140°;—or together with acetate of ethyl, by the action of acetate of lead on chloride of ethyl. It dissolves, though with difficulty, in acetic acid without decomposition, but is decomposed by water, with separation of a small quantity of lead-chloride, and formation of the compound $Pb''Cl^2.3Pb''(C^2H^3O^2)^2$ or $\begin{matrix} (C^2H^3O)^2 \\ Pb^3 \end{matrix}\Big\}\begin{matrix} O^2 \\ Cl' \end{matrix}$ which dissolves in the water, and may be recrystallised without decomposition. It is decomposed, however, by glacial acetic acid, which leaves the original compound. The compound, $\begin{matrix} C^2H^3O \\ Pb'' \end{matrix}\Big\}\begin{matrix} O \\ Cl' \end{matrix}$ is analogous to glycolic chloracetin, $\begin{matrix} C^2H^3O \\ (C^2H^4)'' \end{matrix}\Big\}\begin{matrix} O \\ Cl \end{matrix}$ (ii. 568), and may therefore be called **plumbochloracetin**. (**Carius**, Ann. Ch. Pharm. cxxvii. 87.)

LEAD, CHLOROCARBONATE OF. $2PbCl.Pb^2CO^3$, or $\begin{matrix} (CO)'' \\ Pb^2 \end{matrix}\Big\}\begin{matrix} O^2 \\ Cl^2 \end{matrix}$.—This compound is produced as a white insoluble powder, by boiling 1 at. carbonate of lead with 2 at. (or more) of the chloride, and water. It also occurs native, though rarely, as **corneous lead** or **kerasin**, in acute quadratic pyramids in which P : P in the lateral edges = 113° 48′, and in the terminal edges = 107° 22′. Observed faces $\infty P\infty$, P, ∞P, P and others. Cleavage distinct parallel to ∞P. The mineral likewise occurs in botryoïdal and stalactitic forms. Hardness = 2·5 to 3·0. Specific gravity = 6·0 to 6·1. Colour white, grey, and yellow. Streak white. Transparent to translucent. Fracture conchoïdal. Rather sectile. It occurs at Crawford, near Matlock in Derbyshire, in minute crystals at a lead mine near Elgin in Scotland, and at Tarnowitz, in Upper Silesia, where also large pseudomorphs of lead-carbonate (cerusite) in the form of this mineral are found.

Both the natural and the artificial compound fuse readily, and are converted at a higher temperature, with loss of 7·5 per cent. CO^2, into the oxychloride, $PbCl^2.PbO$.

LEAD, CHLORIODIDE OF. Obtained in pale yellow four-sided needles, from a solution of the iodide in boiling hydrochloric acid; it is gradually decomposed by water, which extracts the chloride of lead. (**Labouré**, J. Pharm. [3] iv. 328.)

LEAD, CHLOROFLUORIDE OF. PbClF.—Formed by precipitating aqueous fluoride of sodium with a boiling solution of chloride of lead, or with a mixture of acetate of lead and chloride of sodium. It is a white powder, which melts when heated, without giving off water or acid. Dissolves in water without decomposition, and easily in nitric acid. (**Berzelius.**)

LEAD, CHLOROPHOSPHATE OF. When a boiling solution of chloride of lead is poured into a boiling solution of phosphate of sodium, the latter being in excess, a precipitate containing $PbCl^2.Pb^3(PO^4)^2.H^2O$ is formed, insoluble in water, but soluble in nitric acid, which converts it into a nitrophosphate (**Heintz**, Pogg. Ann. lxxiii. 122). When, on the contrary, a boiling solution of phosphate of sodium is poured into an excess of chloride of lead, a precipitate is formed which, according to **Heintz**, is composed of $PbCl^2.2Pb^3(PO^4)^2$, but according to **Gerhardt** (Ann. Ch. Phys. [3] xxii. 505), of $PbCl^2.Pb^2H^2(PO^4)^2$. The same compound is formed when a soluble phosphate is precipitated by a lead-solution in presence of a soluble chloride.

The compound $PbCl^2.3Pb^3(PO^4)^2$ occurs native as **pyromorphite**, sometimes pure, sometimes having part of the phosphorus replaced by arsenic, sometimes associated with fluoride and phosphate of calcium. (See **Pyromorphite.**)

LEAD, CHLOROPHOSPHITE OF. Lead-salts added to a solution of alkaline phosphite, obtained by dissolving trichloride of phosphorus in water, and neutralising with an alkali, throw down a precipitate containing a compound of chloride and phosphite of lead, from which boiling water extracts the former.

The reactions with sulphydric, sulphuric and hydrochloric acids, taken
serve to distinguish lead from all other metals. The reactions with iodide and
of potassium are also very characteristic.

III. *Quantitative Estimation.*

1. *Gravimetric methods.*—Lead is generally most conveniently est
sulphate. The concentrated solution is mixed with a slight excess of *dilute sulp*
and about twice its volume of alcohol, filtered after a few hours, the precip
washed with alcohol, and dried, and the filter burnt off. Or, a considerable
sulphuric acid may be substituted for the alcohol, in which case the wash-w
be also acidulated with sulphuric acid, and the last washings displaced by a
burning off, as much of the precipitate as possible is to be detached from
which should be burnt separately, to guard against reduction of lead. In a
is safest to employ a porcelain crucible.

2. Lead may also be weighed as oxide, into which it may be converted d
ignition, or after previous precipitation as oxalate or carbonate (results lo
chromate on a tared filter.

Digitized by Google

Volumetric methods.—Many methods have been proposed for the volumetric estimation of lead, but the greater number give only approximate results. 1. Flores Domonte adds to the lead-solution a quantity of caustic potash or soda sufficient to redissolve the lead-oxide at first precipitated, and then adds to the boiling liquid from a burette, a graduated solution of *sulphide of sodium* as long as a precipitate is thereby produced. The greater part of the sulphide of lead cakes together, but the liquid remains brownish, so that it is difficult to see when the precipitation is complete. The method is, however, useful for technical purposes. The strength of the solution of sulphide of sodium must be determined every two days.

2. Margueritte adds to an alkaline lead-solution, a graduated solution of *permanganate of potassium*, which throws down the peroxides of lead and manganese, continuing the addition till the liquid exhibits a permanent green colour. The solution bumps very strongly when boiled, and the ready alterability of the solution of the permanganate necessitates frequent titration.

3. Pappenheim, according to Mohr, adds to the lead-solution a graduated solution of *sulphate of potassium*, till the liquid no longer produces a yellow spot of iodide of lead on paper prepared with solution of iodide of potassium. This method yields nearly exact results.

4. Streng (Ann. Ch. Pharm. xcii. 413) supersaturates a solution of a lead-salt, or sulphate of lead suspended in water, with potash; adds an excess of solution of *chloride of lime*, and boils for a while, whereby the lead is entirely converted into peroxide. The precipitate is collected on a filter and washed with hot water; a hole is then made in the bottom of the filter, and the precipitate washed through into the vessel in which it was formed; solution of *stannous chloride* is passed through the filter from a burette till all the peroxide of lead is washed off; the filter is again washed with hot water; and an excess of the tin-solution is added, whereby the peroxide of lead is converted into chloride, which is then dissolved by heating it with water and hydrochloric acid. If the excess of *stannous chloride* in the liquid be then determined by means of a standard solution of chromate of potassium, the whole of the data for calculating the amount of lead present in the liquid under examination will be obtained. This method is exact and often convenient.

5. The following process, given by Hempel (Jahresber. 1853, p. 627), is, however, simpler, and has the advantage of admitting of a double verification. The lead is precipitated with a measured quantity of a graduated solution of *oxalic acid* added in excess; the liquid is neutralised with ammonia, and the precipitate collected on a filter; the amount of oxalic acid in the filtrate is then determined by means of a standard solution of *permanganate of potassium*, and by deducting this amount from the total quantity of oxalic acid used, the quantity of oxalic acid combined with the lead is found, and thence the amount of the lead may be calculated.

The result may be checked, either by digesting the precipitate in dilute sulphuric acid, which sets the oxalic acid free, and estimating the amount of oxalic acid in the filtrate with a solution of permanganate — or by igniting and weighing the precipitate.

Mohr completes the determination without filtration. He adds to the solution, in a flask holding 300 cubic centimetres, a drop of tincture of litmus; then adds, from a burette, a standard solution of oxalic acid as long as a white precipitate is formed; saturates with ammonia till the liquid turns blue; fills the flask with water; leaves the liquid to stand for about half an hour till it is sufficiently clarified to allow of 100 cubic centimetres being removed clear with the pipette; and determines the free oxalic acid therein by means of a solution of permanganate, the quantity of which, multiplied by 3, gives the data required for determining the quantity of oxalic acid added in excess. It appears, however, that a small quantity of nitrate of lead is always precipitated together with the oxalate, so that the quantity of oxalic acid used always appears too small. Mohr estimates the errors thence arising at 2 per cent. (Handw. d. Chem. 2te Aufl. ii. [2] 33). On the whole, the volumetric methods of estimating lead do not appear to be so advantageous as the gravimetric methods.

IV. *Separation of Lead from other Metals*

From all metals, not precipitable as sulphides in acid-solution, lead may be separated, by passing *sulphydric acid gas* to saturation through the solution, previously made moderately acid with hydrochloric or nitric acid. The solution should also be moderately dilute. If no other metal, precipitable by the gas, be present, the precipitate will be sulphide of lead with an uncertain quantity of sulphur. If this is deflagrated with nitre, and the sulphur estimated as sulphate of barium, the difference between its weight and that of the precipitate, thoroughly dried at 100°, will give the lead. Or, by oxidising the precipitate in a porcelain vessel with fuming nitric acid, after detaching

Digitized by Google

it as much as possible from the filter, burning the filter, and adding the ash, v
a mixture of sulphate of lead with a little nitrate. This may be converted into
by a slight excess of pure concentrated sulphuric acid; the precipitate is the
and weighed, and the lead calculated therefrom.

Of the metals precipitable by sulphydric acid, gold, platinum, arsenic, antimony may be further separated by digestion of the mixed sulphides in of ammonium containing an excess of sulphur. If, after this treatment, any mercury, bismuth, cadmium, or copper be left with the lead-sulph may be separated by one of the two following methods:—

If no bismuth is present, the solution containing the mixed oxides, is tre *carbonate of sodium*, and then digested with *cyanide of potassium*, when, on carbonate of lead will remain alone on the filter.

From bismuth, the lead may be separated by the following method, a also to its isolation from mercury, copper, and cadmium, but not from present in any quantity:—Evaporate with excess of sulphuric acid until fume appear, cool, and dilute with water; filter at once from the sulphate of lead; v acidulated water and alcohol; then dry and weigh.

The method of precipitation by sulphuric acid, or a soluble sulphate, serve to separate lead in solution without any preliminary treatment, from all m cepting barium, strontium, and calcium (and perhaps silver, *vid. sup.*), and fi earth-metals it is easily separated by sulphydric acid.

In alloys, lead may be very conveniently separated from bismuth, tin, and a and with rather more difficulty from arsenic, by converting all the metals into s and heating the sulphides in a stream of dry *chlorine gas;* all the other m then be volatilised, the lead alone remaining.

V. *Valuation of Lead Ores.*

a. By the wet way.—A very convenient process for determining lead in pecially in galena, consists in oxidising them with fuming nitric acid, adding acid in considerable excess to the slightly diluted solution, filtering and wa residue, as before directed, and after weighing, boiling it repeatedly with solution of acetate of ammonium, which dissolves the lead-sulphate. The residue deducted from the first weight gives the amount of lead-sulphate, fr the lead may be calculated.

b. By the dry way.—For the purposes of assaying, lead ores may be div two principal classes:—

A. Ores &c. which contain no sulphur, arsenic, or phosphorus.
B. Ores containing one or more of the above elements.

A. *First class.*—In the assay of these ores, two points require attention with a reducing agent for the separation of the lead, and with an alkali facilitate the formation of a clean button. Charcoal and argol are among reducing agents; carbonate of sodium, borax. deprived of its water by previo and salt, are useful as fluxes. Black flux, or a mixture of carbon in a fi division with carbonate of potassium, may also be employed. The following will give some idea of the proportions in which these reagents should be but they must, of course, vary somewhat for different ores:

	Sample.	Argol.	Charcoal.	Carbonate of sodium.	Borax glass.	S
No. 1.	200 gr.	100	. .	300	. .	200–2
2.	400 „	200	. .	400	200	
3.	400 „	200	. .	400	200	
4.	400 „	. .	50–60	600	. .	
5.	400 „	200	. .	400	. .	
6.	400 „	600	black flux, and a cover of borax			

1. Recommended by Mitchell for oxides, carbonates, cupel-products, &c.
2. „ „ cupel-bottoms and other refractory prod
3. „ „ fumes, siliceous slags, &c.

4, 5, 6. Phillips:—The salt is not mixed with the other reagents, but to cover the whole mixture.

Ores of this class may also be assayed by the following process, propos writer:—Weigh out 50 grs. of ore on a counterpoise. Fuse, at a red heat, ounce of crude cyanide of potassium in a crucible capable of holding at le the quantity; when fused remove it from the furnace, and add the ore in smal

Digitized by Google

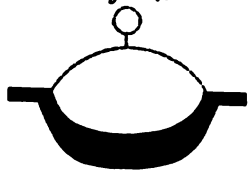
with a spatula; rinse the last traces off with a little more cyanide, and replace it for a minute or two in the fire, then take out the crucible, and tap to collect the lead into a button.

B. *Second class.*—Galena, pure, and mixed with gangue, is included in this class, for the assay of which several methods, more or less accurate, are employed, as—

1. *Roasting the galena*, by which it is converted into oxide, and treating the product as an ore of the first class. This process, besides being exceedingly troublesome, gives little more than three-fourths of the lead actually present.

2. *Fusion with* 3–4 *parts of alkaline carbonate;* the mixture to be heated slowly till fused, which gives about 90 per cent. of the lead present.

3. *Fusion with carbonate of sodium and nitre*, by which the sulphur of the ore is removed as sulphate of potassium; if an excess of the nitrate is employed, a portion of the lead is oxidised and lost. Several assays must therefore be made to discover the best proportions. This process answers very well for obtaining a button to be afterwards assayed for silver, in which case a slight excess of nitre must be used to ensure complete oxidation of the sulphur, without which some silver is liable to be retained as sulphide in the slag.



4. *Fusion with metallic iron*, which has been variously modified as to details. The oldest plan is that given by Berthier, in which the galena is simply mixed with about 30 per cent. of finely divided iron, covered with a layer of some flux and heated; it gives an amount of metal 7–10 per cent. below that actually present. Small iron nails are also recommended by Berthier, which is not a satisfactory process, as the nails become fixed in the button. Mitchell suggests the use of tenpenny nails; Phillips, of iron crucibles, and lastly, a mixture of iron-oxide with a reducing flux. Of these different modifications, the process of Mitchell is especially useful on account its simplicity and accuracy. We extract Mr. Mitchell's own description in full:

"To 200 grains of finely pulverised galena add 50 of argol, and 200 carbonate of soda; place the mixture in a crucible, the inside of which has been smeared with black-lead; introduce three tenpenny nails head downwards; tap the crucible on the mixing bench, so that the contents may occupy as little space as may be; cover with about 200 grains of salt, over that 200 grains of borax. Prepare two crucibles thus, place them in the furnace, and raise the heat rapidly to nearly a bright red; uncover the furnace, and allow the crucibles to remain for 8–10 minutes; again cover the furnace and raise to a bright red: the crucibles will then be ready for removal. Besides the time occupied, the termination of the assay may be judged by the flux flowing smoothly. When this occurs, seize hold of the crucible with the large tongs, and with a smaller pair take hold of one of the nails; rinse it well in the flux to remove any small globules of lead; and then reject it. The two other nails are to be treated in the same way, the crucible removed, tapped on the furnace top to collect all globules, and set aside to cool. So also with the second crucible. When cold they are broken, &c., as usual; the assays should correspond within one-eighth of a grain."

The following is an account of the process employed in the lead-works of North and South Wales, as an example of the rougher methods often adopted in smelting works with good practical results.

In the Welsh lead-works, the assays are generally made on 10 ounces of the ore as received, wet or dry. This is melted in a stout iron dish (*fig.* 637) with a cover, in a smithy fire; when melted, the slag is skimmed back and the produce weighed, each ounce representing 10 per cent., and each dwt. ¼ per cent. In the assay of galenas, some modification may be required; according to Mitchell, by fusing antimonial galenas with carbonate of sodium, pure lead is obtained, but with black flux, the lead contains much antimony; and if iron, either alone or mixed with black flux, be employed, all the antimony is obtained with the lead; but repeated tentative assays must be made to obtain the best possible result. When a lead ore contains oxidised compounds of sulphur and arsenic, reducers alone will not answer; but if they are mixed with an alkaline carbonate and metallic iron, good results are obtained. The assay may be conducted as in Mitchell's process for galenas.

Fig. 637.

A notable loss of lead is sustained in all the above processes, arising chiefly from the volatility of this metal and its oxide: hence the necessity of making all lead-assays at the lowest temperature compatible with perfect fusion, and of not keeping the assay in the furnace longer than is actually necessary. An error in the opposite direction may arise from the presence of foreign metals in the ore, which are more or less completely reduced and alloyed with the lead, increasing its weight; such, for example, as silver, copper, tin, or antimony. Zinc is completely removed if the heat

Digitized by Google

be sufficient, but it entails a loss of lead. Iron does not go down with the
the assay be much overheated. The separation of most of these metals fr
the dry way, is impracticable, with the exception of silver in argentiferous
will bed escribed under *Cupellation* (see below).

Whatever process is employed to determine the lead, some standard is
the manufacturer, to which to refer in calculating the value of the ores. F
in Wales the "standard" is 77 per cent. or 7 oz. 14 dwts. on the assay. T
this standard fluctuates with the market price of lead, and for every variati
or half a per cent. an established addition or deduction is made in the p
silver present is calculated in ounces on the ton, and paid for per ounce.

The following tables have been constructed to save trouble in calculating
of assays:—

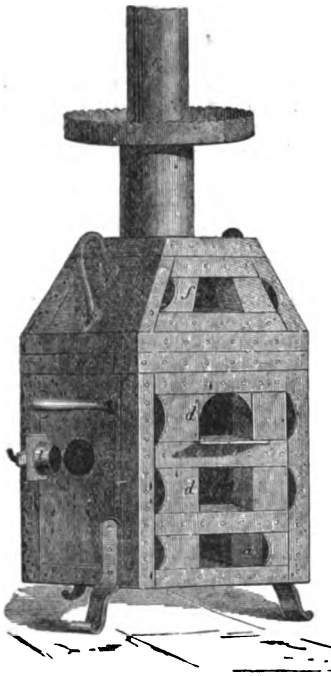
Estimation of the Silver.—The separation of lead and silver in the dry w
process known as cupellation, depends on the fact, that while lead, when
the air at temperatures above its melting point, is rapidly oxidised, silver rem
tered. If, therefore, an argentiferous lead is heated in a current of air, on a
such a texture that the litharge formed from the lead shall be absorbed
produced, the silver will be finally left in the form of a button. This suppo
the "cupel," a flat, slightly hollowed-out dish of pounded bone-ash, compr
mould into the proper form. The process is conducted in a furnace, such as i
figs. 638, 639, where *a* is the ash-pit door; *d'* and *f*, doors for supply of fuel; *d*
ing by which access is obtained and the supply of air regulated to the muffl
muffle is a small fire-clay oven, situated in the centre of the fire, and pierced by
sides and inner end, which, when the door is opened, establish a current of a
the apparatus, while it is maintained at any desired temperature by means of
In using the apparatus, the muffle is first raised to a red heat; 4 to 8, or more,
cupels are then introduced, and the door closed. When they have attain
red heat, the door is opened, a button of lead is placed in each cupel by tong
door again closed. On opening it partially, the buttons are seen "uncovere
senting a bright metallic surface, and a dark ring instantly begins to form
circumference of the lead, as the litharge formed by its oxidation is absorb
cupel, the rings gradually extending as the buttons diminish. The moment
oxidation is completed and pure silver left, is recognised by a peculiar ph
known as the "brightening" of the silver button, which appears, for a
to revolve rapidly on its axis, while covered with a play of prismatic colo
play of colours disappears, and the button becomes still and lustrous.
withdrawn from the furnace, detached from the cupel, cleaned, and wei
balance turning with ·001 gr. Simple as the process appears, some
required, and many points demand attention, before uniform results can be

Digitized by Google

The temperature should be the lowest at which the assay will proceed steadily, as a sensible amount of silver is volatilised with the vapour of lead. The temperature, on the other hand, must not be reduced *too* low, as the absorption of the litharge by the cupel is then impeded. Again, the draught, if too rapid, cools the cupel unduly, and if too slow, does not effect the oxidation with sufficient rapidity, thereby increasing the loss by volatilisation. Further, the absolute quantity of silver remaining the same, if the quantity of lead be much increased, the loss in silver will be greater. But, if the silver-lead be very rich, a loss will arise from the absorption of the alloy into the pores of the cupel. When the heat is too great, the cupels are whitish and the metallic matter they contain can scarcely be seen; the fume is scarcely visible, and rises rapidly

Fig. 638.



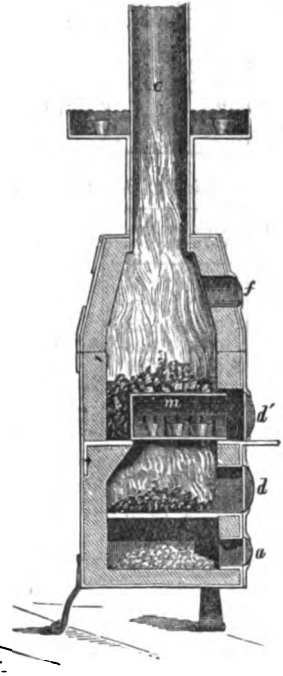


Fig. 639.

to the arch of the muffle. When the heat is not strong enough, the smoke is thick and heavy, falling in the muffle, and the litharge can be seen forming lumps and scales about the assay. When the heat is properly managed, the cupel is red, and the fused metal luminous and clear.

Lastly, a source of loss arises from what is termed "vegetation" of the button, which is due to the absorption of oxygen by the molten metal. When the metal is cooling, in a button of any size, the surface cools and solidifies before the centre has abandoned its mechanically dissolved gas, which, when it is liberated, forces its way through the external crust, raising it into fantastic arborescent forms, which, once seen, sufficiently explain the term. But as portions are frequently projected outwards by the sudden action, it is necessary to cover the cupel, while still hot, with a previously heated old cupel to secure its very gradual cooling. It is only, however, in the case of buttons much larger than a pin's head that this precaution is essential. The weight of the cupel ought to be about one-third greater than that of the lead to be cupelled; a good cupel will absorb its own weight of litharge under ordinary circumstances.

Lead is not the only metal which may be separated from silver by this process. Bismuth may be perfectly "cupelled," and copper, antimony, iron, tin, &c., may be "passed" by the addition of sufficient lead to carry their oxides into the cupel.

The following tables are useful in an assay office, where numerous assays are made from time to time, and they are constructed for different weights of lead cupelled, as well as the produce per 20 cwt. or ton and per 21 cwt. or fodder of lead:—

VI. *Atomic Weight of Lead.*

The atomic weight of this metal has been determined chiefly by the experin
Berzelius, made in 1830 and 1845 (Pogg. Ann. xix. 300; *Lehrbuch*, 5te Aufl. iii
By reducing pure protoxide of lead with hydrogen gas, he found that 100 pts
protoxide contain 7·1724 pts. oxygen, whence, regarding the protoxide as Pb
putting oxygen = 16, the atomic weight of lead is 103·54; if, however, a certain
of the determinations, which do not agree very well with the rest, be left out of a
the atomic weight is found to be 103·57. The extreme limits of the determi
in question were 103·36 and 103·65. Within the same limits also are compri
older determinations of Berzelius (1818), which gave 103·56; also those of T
in 1835 (Ann. Ch. Pharm. xiii. 14), which gave 103·61, and nearly also t
Longchamp in 1827 (Ann. Ch. Phys. [2] xxxiv. 105), which gave numbers
from 103·64 to 103·74. The mean of all the best determinations is 103·56; or

be regarded as diatomic, and the protoxide be represented by the formula $Pb''O$, then the atomic weight is 207·12. T. R.

LEAD, FLUORIDE OF, PbF^2, is obtained by precipitating acetate of lead with hydrofluoric acid, or by decomposing carbonate of lead with the same acid, as a white powder, sparingly soluble in water, easily fusible, soluble in hydrochloric and in nitric acid, by which it is decomposed on evaporation. When treated with aqueous ammonia or fused with oxide of lead, it is converted into a more soluble **oxyfluoride**, the solution of which has an astringent taste, and on standing in the air, deposits carbonate of lead, mixed or combined with fluoride of lead.

A **chlorofluoride** of lead has been already described (p. 539).

LEAD, HYDROALUMINOUS. See PLUMBORESINITE.

LEAD, IODIDE OF, PbI^2, is obtained by precipitating nitrate of lead with iodide of potassium, avoiding an excess of either salt. It is a precipitate of a fine light yellow colour; soluble in 1,235 pts. of cold water (Denort), and in 194 pts. of boiling water, forming a colourless solution, whence it crystallises on cooling in flexible, six-sided, laminar crystals. It is obtained in the same form by mixing the solutions of iodide of lead and iodide of potassium at the boiling heat. It is not more soluble in water containing acetic acid than in pure water. According to Henry, it is not quite insoluble in alcohol. Ether, according to A. Vogel, extracts iodine from it, leaving oxyiodide of lead. It dissolves in cold, and still more in warm aqueous sal-ammoniac, and crystallises therefrom on cooling in yellowish white needles (Boullay). In caustic ammonia, nitrate, succinate, carbonate, and sulphate of ammonium, it turns white (Wittstein). When boiled with the carbonates of the alkalis or alkaline earths, it yields carbonate of lead and a soluble iodide.

Iodide of lead, when heated, turns reddish-yellow and brick-red, then red-brown, and melts to a liquid of the same colour, which solidifies to a yellow mass. When fused in contact with the air, it gives off a part of its iodine, and leaves an oxyiodide of lead. It is easily decomposed by chlorine. Zinc or iron boiled with it under water takes up the iodine and precipitates metallic lead.

Iodide of Lead and Hydrogen, $PbI^2.2HI$, crystallises from a solution of iodide of lead in warm aqueous hydriodic acid, in concentrically grouped, silky needles, which give off the whole of the hydriodic acid when heated, and part of it even when exposed to the air at ordinary temperatures. The acid may also be extracted by water.

Ammonio-iodide of lead, or *iodide of plumbammonium*, $N^2H^6PbI^2$, is obtained as a white powder by passing ammonia-gas for a long time over finely-pulverised iodide of lead, or by digesting it at ordinary temperatures with sal-ammoniac. It gives off its ammonia spontaneously on exposure to the air, and even in an atmosphere of ammonia when heated.

Aceto-iodide of lead, $PbI.C^2H^3PbO^2$, or $\begin{matrix} C^2H^3O \\ Pb'' \end{matrix}\Big\}\begin{matrix} O \\ I \end{matrix}$, analogous to glycolic iodacetin (ii. 568), is obtained in a similar manner to the corresponding chlorine-compound (p. 539), with which it is isomorphous. (Carius, Ann. Ch. Pharm. cxxv. 87.)

An *iodochloride of lead*, $Pb^3Cl^4I^2$, has been already described (p. 539).

An *iodide of lead and ammonium* is formed, as a white precipitate, on adding iodide of ammonia in excess to nitrate of lead.

A compound of *iodide of lead* with *chloride of ammonium*, $3NH^4Cl.PbI^2$, is obtained by dropping a solution of neutral acetate of lead into a boiling mixed solution of iodide of potassium and sal-ammoniac, as long as no permanent precipitate is formed. On cooling, the double salt crystallises in slender yellow, shining needles, which, however, are decomposed by water, the sal-ammoniac dissolving out first.

Another compound, $2NH^4Cl.PbI^2.2H^2O$, crystallises in white silky needles.

Iodides of lead and potassium.—When 1 at. iodide of lead (PbI^2) and 1 at. iodide of potassium are dissolved in the smallest possible quantity of boiling water, the solution yields on cooling, large yellow, shining, six-sided laminæ, having the composition $KI.PbI^2$, and on dissolving these crystals in a hot solution of iodide of potassium, white silky needles, consisting of $4KI.PbI^2$, are deposited as the liquid cools. Both salts are decomposed by water and by alcohol.

LEAD ORES. The following is a list of minerals containing lead as an essential constituent, and available, when they occur in sufficient quantity, for the extraction of the metal:

Aciculite. Aikinite. Belonite. Needle-ore.

Patrinite. $\begin{matrix} \dot{Pb}^2 \\ (Cu^2)'' \end{matrix}\Big\}S^3.Bi^2S^3$.

Altaite. Telluride of lead. PbTe.

Aluminate of lead (hydrated). Plumboresinite. $\begin{matrix} \dot{Pb} \\ \dot{Al}^4 \end{matrix}\Big\}O^7.6H^2O$.

The ores which are actually worked for lead have been already described (pp. 480, 481): for the rest, see the several articles.—Respecting the working of lead ores, see pp. 481—531; methods of assaying them, p. 543.

LEAD, OXIDES OF. Lead forms five oxides, viz.:

The Suboxide	Pb^2O.
The Protoxide	PbO.
The Red oxide	Pb^3O^4.
The Sesquioxide	Pb^2O^3.
The Dioxide or Peroxide	PbO^2.

The protoxide is a strong base; the sesquioxide and peroxide also unite with acids. The red oxide is decomposed by most acids. All the oxides of lead are easily reduced to the metallic state by charcoal at a red heat.

Suboxide. Pb^2O.—This oxide, which was discovered by Dulong, remains when oxalate of lead is cautiously heated in a retort from which the air is excluded. According to Pelouze (Ann. Ch. Pharm. xlii. 209), the retort should be heated in an oil-bath to a temperature not exceeding 300°, the heat being continued as long as any gas is given off: the gas thus evolved is a mixture of 1 vol. carbonic oxide and 3 vol. carbonic anhydride:

$$2PbC^2O^4 = Pb^2O + CO + 3CO^2.$$

The whole is suffered to cool before the suboxide is removed. It forms a black powder, sometimes dull, sometimes having a velvety lustre. It contains no metallic lead, for mercury extracts nothing from it, either dry or under water; neither does it contain any protoxide, for the aqueous solution of acetate of lead does not extract any protoxide from it on boiling. But when heated to dull redness, out of contact of air, it is resolved into a greenish-yellow mixture of lead and protoxide (Boussingault, Pelouze). After this treatment, mercury extracts lead from the substance, and a boiling solution of acetate of lead or acetic acid leaves the lead in the form of a network, which, when pressed together between the fingers, forms a dense mass having the metallic lustre. The suboxide heated in the air takes fire, burns with a glimmering light, and is converted into protoxide. Dilute *sulphuric, nitric, hydrochloric,* or *acetic acid* resolves it into protoxide, which combines with the acid, and very finely-divided metallic lead. The same effect is produced by a strong solution of *normal nitrate of lead*; a dilute solution, on the contrary, takes up the whole of the suboxide and forms basic nitrate of lead. The suboxide, when moistened with *water*, rapidly absorbs oxygen from the air, and is converted into the white hydrated protoxide, the action being attended with rise of temperature. A mixture of finely-divided lead and litharge does not yield the same result.

The grey pellicle which forms upon lead exposed to the air, has also, according to Berzelius, the composition Pb^2O.

Protoxide. *Lead-oxide.* PbO.—This oxide occurs native as lead-ochre, a massive mineral, sometimes with scaly crystalline structure. Specific gravity 8·0. Lustre dull. Opaque. Colour between sulphur- and orpiment-yellow. Streak lighter than the colour. It does not soil. It is said to occur at Badenweiler, in Baden, and, according to Gerolt, has been ejected from the volcanoes Popocatapetl and Iztaccituall, in Mexico. It is found also at other localities in Mexico, and at Austin's mines, Wythe county, Virginia. (Dana, ii. 109.)

Protoxide of lead is obtained pure by igniting the basic nitrate, or the carbonate or oxalate of lead, in a platinum crucible, in contact with the air, taking care that the oxide does not fuse, otherwise it will take up metal from the crucible, and if heated in a porcelain crucible, would take up silica. The pure oxide thus obtained has a lemon-yellow colour, and a specific gravity of 9·4214.

On the large scale, protoxide of lead is obtained in the forms of massicot and litharge.—1. *Massicot* is prepared by heating lead to low redness on a flat hearth, and continually removing the film of oxide as it forms, till the lead-ash at first obtained is, for the most part, converted into the yellow oxide; the latter is then freed from the still remaining metallic portions by grinding and levigation.—2. *Litharge* is obtained in the oxidation of *pig-lead* containing gold and silver—the resulting lead-oxide, which is

Digitized by Google

generally contaminated with silica, ferric oxide, cupric and cuprous oxide, a oxide, and other oxides, is fused by the high temperature, and solidifies shining mass, sometimes of a yellowish tint (*Argyritis, Silber-glätte*), somet inclining to red (*Chrysitis, Goldglätte*). The oxide of copper may be removed by digesting the levigated litharge with aqueous solution of carbo monia (Bischof, Schw. J. 64, 65).—The antimonious oxide is left behind o the litharge in boiling nitric acid, and may then be dissolved in hydro (Anthon, Repert. 58, 387.)—The difference between red and yellow lithar buted by Leblanc (J. Pharm. [3], Sept. 8, 1845) to a mere diversity structure, not of chemical composition; for either modification may be o pleasure by properly regulating the temperature and the rate of coolin variety, which is specifically lighter than the yellow and more crystalline s formed most abundantly when the cooling is slow. (See also p. 514.)

Properties.—Protoxide of lead appears to be both dimorphous and occurring in pale-yellow rhombic octahedrons and cubes, and regular dod and as a red amorphous powder. By the following processes it may be obta crystalline state:—1. *By slow cooling after fusion.* Litharge, when qui solidifies in a mass of crystalline scales; but the portion which remains on sometimes crystallises in yellow, translucent, six-sided tables (Marx); octahedrons with a distinct plane of cleavage (Mitscherlich); in regu hedrons, the angles of which are indefinite, in consequence of the curva faces (Gaultier de Claubry and Beudant). White lead fused by th flame on a copper plate or other non-reducing support, crystallises in scales but from the middle of it there generally shoots out a mass, half a line long, in the form of a triangular pyramid, sometimes in that of a nearly perfe dodecahedron, of a hyacinth-red tint while hot, becoming sulphur-yellow lucent as it cools, and opaque and dull when perfectly cold. This alternate crystallisation may be repeated several times.—2. *By fusion with hydrate of* If 1 part of lead-oxide and from 4 to 6 of hydrate of potassium be fused time in a silver crucible at an incipient red heat, and the mass after cooling with water, the lead-oxide remains in the form of cubes and square tables (B Ann. Ch. Phys. [2], li. 105).—3. *By treating lead-oxide with potash or soda-* a solution of lead-oxide in soda-ley, saturated while hot, placed in a stopp and then left to itself all through the winter, the lead-oxide crystallises in s translucent rhombic dodecahedrons (Houton-Labillardière, J. Pharm The crystals are trimetric octahedrons, having the same angles as those o fusion (Mitscherlich). Strong boiling potash-ley saturated with lead-o on cooling, yellow scales similar to those of litharge; if the potash-solution saturated with lead-oxide, or if it has deposited the excess of that oxide i further deposition takes place till after perfect cooling, whereupon red scales down, perfectly soluble in acetic acid, and therefore free from minium; if thes heated, they turn yellow on cooling. Hence it appears that litharge may colour without containing minium or red oxide of copper (Mitscherlich, J xix. 451).—Boiling soda-ley of 40°—41° B., saturated with hydrate of l rose-red crystals of the protoxide on cooling. These crystals yield an ora powder, similar to that of litharge. At about 400° they turn black, incre decrepitate with loss of 0·1 per cent. of water—and when heated to lo assume a sulphur-yellow colour without changing their form. While still state, they dissolve, though very sparingly, in nitric acid, either concentrate (Calvert, Compt. rend. xvi. 136). If hydrated lead-oxide be boiled with of aqueous alkali not sufficient to dissolve it, the undissolved portion be verted into crystalline anhydrous oxide; the resulting solution, when evapor more crystals of the anhydrous oxide, distinguished from the former porti easy solubility in alkalis, even when dilute (Frémy, J. Pharm. [3], iii. 3 *precipitating a lead-salt with excess of alkali.* Solution of neutral acet mixed with excess of ammonia and exposed to the sun for a few days, y green, very hard crystals of anhydrous oxide (Tünnermann, Kastn. Arch. Behrens (J. Pharm. [3], iv. 4, 18) supersaturates the sugar-of-lead solut quantity of ammonia sufficient to re-dissolve the precipitate; filters to se carbonate of lead that may have been formed; puts the filtrate into a bottle; and exposes it to the rays of the sun. After a few hours, transpare make their appearance, colourless at first, but afterwards becoming yell finally yellowish-grey. Their powder is white, but assumes a dark brown after long trituration.—4 measures of solution of lead-acetate, saturated at with 100 measures of boiling water, and then with 45 measures of aqueous deposit, in the course of half a minute, a large number of very delicate, yello rhomboïdal laminæ, having a silvery lustre and united in tufts; these lami

Digitized by Google

separated by levigation from the crystalline granules of hydrated oxide, which fall down at the same time, then washed with boiling water, and dried in vacuo. When ignited, they do not give off any water—or only a trace of it, with decrepitation—neither do they lose their transparency. They may be obtained without admixture of hydrate, by boiling 100 measures of a saturated solution of triplumbic acetate with 50 measures of water, adding thereto a mixture of 50 measures of water at 80°, and 8 measures of aqueous ammonia, and heating the mixture in the water-bath. In the course of a minute, crystals of the oxide separate, free from hydrate, the formation of the latter being prevented by the high temperature (Payen, Ann. Ch. Phys. [2], lxvi. 54).—*5. By placing lead in contact with air and water.* On the bottom of a leaden vessel filled with water, there are first formed a number of white flakes of hydrated basic carbonate of lead, then shining grey crystals of anhydrous oxide, partly in scales like mica, partly in rhombic dodecahedrons with cube-faces. When heated, they become opaque and orange-coloured, but without losing weight or lustre. (Yorke, Phil. Mag. [3] v. 82.)

The specific gravity of protoxide of lead is 9·20092 (Karsten), 9·277 (Herapath), 9·363 (Playfair and Joule); after fusion 9·50 (Boullay). According to Leblanc (Ann. Ch. Pharm. lvi. 235), the specific gravity of litharge is greater after slow than after quick solidification. The cubical expansion between 0° and 100° is 0·00795. At a red heat it melts to a clear dark red liquid, which solidifies to a reddish-yellow crystalline mass.

Protoxide of lead unites readily with *acids*, forming neutral and very soluble salts, and likewise exhibits a decided chlorous or negative reaction towards strong *bases*. It dissolves readily in caustic *potash* and *soda*. *Baryta*-water and *lime-water* also dissolve it, and the lime-compound is said to crystallise in sparingly soluble needles. By boiling the protoxide with milk of lime, a liquid is obtained which may be used for producing a black dye on hair, nails, horn, and wood.

An *oxide of lead and silver*, $Ag^2O.2PbO$ or $Ag^2Pb^2O^3$, is obtained by adding caustic potash to a solution of a lead-salt mixed with a silver-salt, as a yellow precipitate insoluble in excess of the alkali, and thereby easily separated from admixed lead-oxide. It is easily soluble in nitric acid; blackens on exposure to light; leaves, when ignited, a mixture of lead-oxide and metallic silver; and when quietly heated in hydrogen gas is reduced to an easily fusible alloy of the two metals. (Wöhler, Pogg. Ann. xli. 344.)

Protoxide of lead dissolves, according to Bineau, in 7,000 pts. of pure water, forming a solution which decomposes most salts of the alkali-metals. The solubility is greatly diminished by the presence of certain salts, *e.g.* sulphates, phosphates and carbonates, and increased by that of ammonia and its salts (p. 47).

Hydrate, or *Hydrated Oxide of Lead*, is obtained on adding a solution of neutral acetate of lead to excess of ammonia, as a white amorphous precipitate containing $3PbO.2H^2O$ (Payen), or $2PbO.H^2O$ (Schaffner), or, according to older statements, $PbO.H^2O$ or PbH^2O^2. If the solution be heated, the anhydrous protoxide is formed at the same time. When lead is immersed in pure water, hydrate of lead is formed, and partly dissolves (v. Bonsdorff). The hydrate precipitated on treating nitrate or acetate of lead with caustic potash is always mixed, according to Winkelblech, with a certain quantity of basic salt. According to other statements, however, the acid which it contains may be completely removed by digestion with a slight excess of alkali.

The hydrate prepared by precipitation with ammonia, as above, appears under the microscope to be composed of prismatic crystals. It must be protected from the air during washing, otherwise it will absorb carbonic acid. It retains its water at 100°, but gives it up at a somewhat higher temperature, and is converted into the anhydrous protoxide, which is red while hot, yellow after cooling.

Hydrate of lead takes up *ammonia*, forming the two compounds $2NH^3.PbO.H^2O$ and $2(NH^3.4PbO).H^2O$. (Calvert, Compt. rend. xxii. 480.)

Red Oxide of Lead. *Red Lead. Minium.* $Pb^3O^4 = 2PbO.PbO^2$ or $PbO.Pb^2O^3$.—This oxide is formed when the protoxide is kept at a low red heat for a considerable time in contact with the air; also, after previous formation of hydrated protoxide and basic carbonate of lead, when lead-shavings are strewn upon water, the vessel being loosely covered, and then set aside for some months, the formation of red lead taking place chiefly on those surfaces of the metal which are exposed to the air. In like manner, drawings made with lead turn red in the course of years. (v. Bonsdorff.)

The red oxide also occurs native in certain localities, mixed with other ores of lead, and probably resulting from their oxidation, viz. at Bleialf and Kall in the Eifel, at Badenweiler in Baden; at Brillon in Westphalia; on Grassington Moor, and in Weirdale, Yorkshire; in the Isle of Anglesey, and at Austin's Mine, Wythe County, Virginia, where it accompanies cerusite.

Digitized by Google

Red lead is extensively used as a pigment, and in the manufacture of flint It is prepared on the large scale in this country, chiefly in Derbyshire, by ox lead in a reverberatory furnace having two *fire-hearths*, covered by an ellip arched roof; they are situated at the extreme end of the furnace, and are sep from the middle hearth, or *lead-hearth*, by low walls or fire-bridges. The fuel coke. About 1,500lbs. of lead (one-tenth consisting of hard lead) are placed up lead-hearth, and worked about, as soon as it is melted, with an iron crutch, the (massicot) as it forms being pushed to the side of the hearth. The tempe must not be raised above low redness, so that the oxide may not melt. A hours, the massicot is taken out, reduced, to very fine powder by grinding and tion, again placed upon the lead-hearth, and exposed to the same temperat before for 48 hours, or till a sample taken out appears dark red when hot, and red on cooling. The furnace must then be closed, and left to cool slowly, a co mainly essential to the success of the operation. In Germany the conversion massicot into red lead is effected in a peculiar furnace, in which the massicot is not on a hearth, but in barrel-shaped vessels open at both ends. Sometim operation is repeated in order to improve the colour. Carbonate of lead may used, instead of massicot, for conversion into red lead, but when the temperat properly regulated, another pigment is obtained, called *Orange Lead*. Red lea prepared, which, however, retains a little carbonic acid, is known as a pigment name of Paris red.

To free commercial red lead from the yellow oxide mixed with it, Dumas dig repeatedly with solution of lead-acetate; Berzelius and Dalton recommend tre with cold, very dilute acetic acid; Phillips recommends 144 pts. at most, of acetic acid diluted with a large quantity of water to 100 of minium, inasmuc more acid be used, the brown peroxide is likewise formed. According to I however, peroxide of lead is always formed in the purification of minium, bef whole of the free protoxide is extracted, even when the dilutest acetic acid is em

Commercial red lead likewise contains all the foreign metallic oxides—such oxides of copper, iron, and silver—with which the massicot or litharge used i paring it is contaminated. Red lead is likewise often adulterated with oxide o red bole or brick-dust; these substances remain undissolved when the red lead gested in warm dilute nitric acid; boiling hydrochloric acid extracts sesq of iron from the residue. When red lead thus adulterated is ignited, there re mixture of yellow lead-oxide and the red substances that have been added to it

On the small scale, red lead may be obtained of very fine colour by the fol processes:—1. When 4 pts. of lead-oxide, prepared by igniting white lead, are in a silver or platinum crucible with 1 pt. of chlorate of potassium and 8 pts. o (the latter acting as a flux and thereby saving the chlorate), brown peroxide of first obtained; but this, when further heated to dull redness, is converted, wit mescence and thickening of the mass, into red lead. As soon as the red lead to decompose at the edge of the crucible, the mass is suffered to cool, and the r well boiled with water containing potash.—2. By boiling peroxide of lead with a plumbate of potassium, or 1 pt. of the peroxide with 5 pts. of lead-nitrate quantity of aqueous potash or soda sufficient to redissolve the hydrate of lead fi cipitated, till a brown-red mixture of minium with a small quantity of the pero produced, and digesting this mixture, after washing, with oxalic acid, which poses the peroxide without acting on the minium. The minium obtained process is rather dark-coloured, but becomes brighter when rubbed up with wa has the same composition as that which is obtained by the ordinary method. (Ann. Ch. Phys. [3] lxxv. 108.)

Properties.—Red oxide of lead is a scarlet, crystalline-granular powder; heated, it first assumes a finer red colour, and then turns violet. Specific gravi (Karsten), 8·94 (Muschenbroek), 9·082 (Herapath); of native minium 4·6 (Dana, ii. 126.)

Red lead was formerly supposed, according to analyses by Richter, Wi Thomson, and Berzelius, to be a sesquioxide, Pb^2O^3; but it is probable t products examined by these chemists contained protoxide or carbonate of le Dumas has shown that the perfectly pure red oxide specially prepared for ana the commercial product freed from protoxide by digestion with solution of ac lead, contains 90·63 per cent. lead and 9·37 oxygen, numbers agreeing exactly v formula Pb^3O^4. It may be regarded either as a compound of the protoxide a oxide of lead, $2PbO.PbO^2$, or perhaps of the protoxide and sesquioxide, PbO analogous to magnetic oxide of iron. Jacquelain (J. pr. Chem. liii. 151) fou a mixture of 1 at. PbO and 1 at. PbO^2, heated to 450°, assumed a fine red gave off no oxygen, and was afterwards perfectly soluble in potash-ley and acetic acid. It is possible, however, that there may be more than one red o

lead intermediate in composition between the proto- and peroxides; for a crystallised red lead from a minium furnace, analysed by Houton-Labillardière, exhibited the composition $3PbO.PbO^2$.

Decompositions.—1. By rather strong ignition, red lead is resolved into the protoxide and 2·4 per cent. of oxygen gas (Dumas).—2. By many oxidable bodies, at various temperatures, it is reduced to the protoxide. Aqueous *sulphurous* and *nitrous* acids, at ordinary temperatures, convert it respectively into sulphate and nitrate of lead; *sulphurous acid* acts very slowly in the cold, but rapidly on the application of heat. *Dichloride of tin* converts it, with a rise of temperature of 13°, into chloride of lead and stannic oxide (A. Vogel, Kastn. Arch. xxiii. 84). It is likewise reduced by boiling with a solution of *sugar*, and oxidises many organic acids. When 2 pts. of red lead and 1 pt. crystallised tartaric acid are rubbed up to a thin paste with a small quantity of water, the mixture becomes hot and whitish, and the odour of formic acid is given off (Böttger).—3. By a small quantity of *hydrochloric acid*, red lead is converted into chloride of lead, peroxide of lead, and water:

$$Pb^3O^4 + 4HCl = 2PbCl^2 + PbO^2 + 2H^2O.$$

By a larger quantity of hydrochloric acid, into chloride of lead, chlorine gas, and water:

$$Pb^3O^4 + 8HCl = 3PbCl^2 + Cl^2 + 4H^2O.$$

4. By *chlorine-water*, into chlorine and peroxide of lead:

$$Pb^3O^4 + Cl^2 = PbCl^2 + 2PbO^2.$$

Similarly with *bromine-water* (Löwig). Minium is not decomposed by mercurous nitrate or oxalic acid. (Levol.)

Heated with *strong sulphuric acid*, it yields sulphate of lead and free oxygen. By *nitric acid*, *dilute sulphuric acid*, and likewise by weaker acids, such as ordinary *acetic acid*, it is resolved into protoxide and peroxide, the former dissolving in the form of an ordinary lead-salt, while the latter remains undissolved. In *glacial acetic acid*, however, it dissolves completely; and when considerable quantities of it, but not quite sufficient for saturation, are dissolved in that acid at 40°, the liquid on cooling deposits prismatic crystals of acetate of peroxide of lead, while an acetate of the sesquioxide remains in solution (Jacquelain, J. pr. Chem. liii. 151). According to Schönbein (*ibid.* lxxxiv. 315), concentrated acetic acid shaken up for about 15 minutes with levigated minium, takes up about 9 per cent. of it, forming a solution which is quickly decomposed by heat or by dilution, but appears to be stable at −18°. Sulphuric acid added to this solution throws down all the protoxide of lead contained in it, leaving a pure solution of acetate of peroxide, which deposits the peroxide slowly at ordinary temperatures, quickly when warmed. Potash added to the solution of minium in acetic acid, throws down, not minium, but a mixture of the proto- and peroxides, which blues tincture of guaiacum and iodised starch-paste, reactions not produced by pure minium. The solution of minium, and that of the pure peroxide in acetic acid, immediately decolorise solution of indigo; when shaken up with finely divided zinc, iron, lead, copper, or even silver, they form acetates of these metals and lose their oxidising properties. The same solutions convert iodine into iodic acid, sulphurous acid into sulphuric acid, sulphide of lead into sulphate, and act strongly at common temperatures on oil of turpentine. (Schönbein.)

Minium likewise dissolves in cold concentrated aqueous *phosphoric* and *arsenic acids*, forming salts of the peroxide. (Jacquelain, see p. 555.)

Sesquioxide of Lead. Pb^2O^3.—Hypochlorite of sodium throws down from lead-salts, a reddish-yellow mixture of sesquioxide and chloride of lead, which, if warmed or left to stand for some time, turns brown from formation of peroxide. To obtain the sesquioxide free from chloride, nitrate of lead is supersaturated with potash in sufficient quantity to redissolve the precipitate, and then treated with hypochlorite of sodium. The yellow precipitate, when washed and dried, yields a soft, non-crystalline, reddish-yellow powder, which may be dried over oil of vitriol. At a red heat, the sesquioxide is resolved into 6·47 per cent. of oxygen gas, and 96·53 per cent. of protoxide. By oxalic acid and by formic acid it is reduced to protoxide, with evolution of heat. With nitric, sulphuric, hydrofluosilicic and acetic acids, generally without the application of heat, it is converted into peroxide and a salt of the protoxide. It dissolves in cold hydrochloric acid, forming a yellow liquid from which it is again precipitated by alkalis: the liquid, however, resolves itself in a few minutes into chloride of lead and free chlorine. (Winkelblech, Ann. Ch. Pharm. li. 176.)

The sesquioxide may also be obtained by precipitating a solution of the red oxide in acetic acid (*vid. sup.*) with caustic alkalis or alkaline carbonates. If the fixed alkalis are used, the sesquioxide always retains a portion of the precipitant, which cannot be removed by washing; but by pouring the acetic solution into very dilute ammonia,

Pattinson prepares this oxychloride on the large scale, for use as a pigme following process:—Finely pulverised galena is heated with strong hydrochl whereby chloride of lead is formed, and sulphydric acid evolved; this gas i in large gasometers, and used for the preparation of sulphuric acid by coml the ordinary lead-chambers. The liquid is allowed to cool completely in co the undissolved residue; this residue, which consists chiefly of chloride of lead, with cold water to remove the easily soluble chlorides of copper and iron, gradually introduced into a vessel containing boiling water, which diss chloride of lead, leaving a smaller residue consisting of gangue, chloride of s undecomposed galena. By melting this last residue with lime, a quantity containing a little lead is obtained, even from ores in which the proportion o too small for profitable extraction, either by the ordinary process of calcinati Pattinson's condensation process. The hot clear solution of chloride of lead as above is mixed with very thin milk of lime, sufficient to neutralise only ha drochloric acid present. A precipitate of oxychloride, Ppb^2Cl^2O, is then form may be used advantageously as a pigment in place of white lead, as it covers mixed with oil, and does not turn yellow in the dark, or blacken from expos containing sulphuretted hydrogen, more quickly than white lead.

c. $Pb^3Cl^2O^2 = PbCl^2.2PbO$.—This compound forms the rare mineral m (also called *berzelite* and *cerasite*) found on the Mendip Hills in Somersetsh it occurs in yellowish-white, trimetric prisms exhibiting the faces, oP, ∞ ∞P∞, and having the angle ∞P : ∞P = 102° 36′. Cleavage very distinc to ∞P; less distinct diagonally. Hardness = 2·5—3. Specific gravity = The crystals are translucent, and have an adamantine lustre on the cleavage- occurs in a state of greater purity at Brilon, near Stadtbergen in Westph crystals there found are white, translucent, and have a mother-of-pearl the cleavage-faces. It is also found in opaque prismatic crystals at Tar Silesia.

d. $Pb^4Cl^2O^3 = PbCl^2.3PbO$.—This compound is obtained in the anhydrou fusing 1 at. chloride of lead with 3 at. of the protoxide; also as a hydrate, H^2O, by decomposing chloride of lead with ammonia; by precipitating bas of lead with common salt; and by decomposing a solution of common protoxide of lead. The hydrate is a white flocculent mass, and when igni the anhydrous compound, which is a greenish-yellow laminated mass, yieldin powder, known as *Turner's yellow*. It is prepared as a pigment, by mixin with ¼ to ⅓ of its weight of common salt, and pouring water on the mixtur becomes hot, swells up, yields a solution of caustic soda containing a v quantity of lead, and a residue of basic chloride, which is washed and ign moderate heat. The hydrated compound was formerly used as a white p place of white lead, being known as *Pattinson's monobasic chloride;* but it much body as white lead.

e. $Pb^6Cl^2O^5 = PbCl^2.5PbO$.—Obtained by fusing chloride of lead with 5 protoxide. Orange-yellow substance, yielding a deep yellow powder.

f. $Pb^8Cl^2O^7 = PbCl^2.7PbO$.—Produced by fusing a mixture of 10 pts. of p of lead and 1 pt. of pure sal-ammoniac, a portion of the lead being at the reduced. The fused product affords cubic crystals on cooling slowly. It forn state a beautiful yellow pigment, known as *Cassel yellow.*

LEAD, OXYCYANIDE OF. See ii. 253.

LEAD, OXYFLUORIDE OF. See p. 547.

LEAD, OXYGEN-SALTS OF. Protoxide of lead is a strong bas readily with acids, and forming salts, the general characters of which have be described (p. 540). Those which are soluble have a sweetish taste and are They resemble the salts of barium and strontium in being readily precipitat phuric acid, and many of them are isomorphous with the corresponding salt metals. Lead has a very great tendency to form basic salts, which may be either as compounds of the normal salts with oxide or hydrate of lead, o derived from two or more molecules of water, in which less than half the h replaced by an acid radicle: thus, there is a basic nitrate of lead

$$Pb(NO^3)^2.PbH^2O^2 \text{ or } \left.\begin{matrix} NO^2 \\ Pb'' \\ H \end{matrix}\right\} O^2,$$

and a tribasic acetate containing

$$Pb(C^2H^3O^2)^2.(PbO)^2 \text{ or } \left.\begin{matrix} (C^2H^3O)^2 \\ Pb''^3 \end{matrix}\right\} O^4.$$

These basic oxygen-salts are analogous to the oxychlori iodides, &c. (For descriptions of the individual salts, see the several Acids

Digitized by Google

The sesquioxide and peroxide of lead also unite with acids, but the salts thence resulting are not very stable. They are produced by the action of certain acids on the red oxide of lead (p. 553).

LEAD, OXYIODIDES OF. Five of these compounds have been described:

a. $Pb^3I^2O = PbI^2.PbO$, is obtained, according to Brandes and Kühne (Pharm. Centralbl. 1847, p. 593), by precipitating acetate of lead with iodide of potassium. Denot (J. Pharm. xx. 1) uses a solution of the neutral acetate mixed with a small quantity of basic acetate, and dissolves out the iodide of lead contained in the precipitate with water. The same compound is said to be formed when iodide of lead is digested for some time in a solution of the neutral acetate. Acetic acid is said to dissolve out the oxide of lead from this compound, leaving the iodide. By immersion in solution of iodide of potassium it is converted into iodide of lead. It contains 1 at. water, which is given off at 100° (Kühne), at 200° (Denot). It melts with partial decomposition at 300°, and solidifies to a clear yellow glass on cooling.

b. $Pb^5I^2O.H^2O = PbI^2.2PbO.H^2O$, is obtained, according to Kühne, by digesting levigated oxide of lead with a boiling solution of iodide of potassium as long as it continues to increase in weight. By precipitating basic acetate of lead with iodide of potassium, Kühne obtained nothing but the compound *a*, whereas Denot states that compounds containing 2 at. and 5 at. oxide of lead to 1 at. iodide are obtained by precipitating iodide of potassium with dibasic or pentabasic acetate of lead.

c. $PbI^2.3PbO.2H^2O$.—Obtained by treating a boiling solution of iodide of lead with caustic ammonia. (Kühne.)

d. $PbI^2.2PbO.Pb^2O^3$ (?).—This is a wine-red compound, obtained by triturating recently precipitated hydrate of lead with a fourth of its weight of iodine, and boiling with water as long as fumes of iodine are given off. (Jammes.)

e. $PbI^2.6PbO$.—Remains in the form of a yellow powder when the compound *d* is dried and heated. (Handw. d. Chem. 2te Aufl. ii. [2], 60.)

LEAD, PHOSPHIDE OF. *a.* When phosphorus is thrown upon melted lead, or when lead-filings are ignited with an equal weight of glacial phosphoric acid, or chloride of lead with phosphorus, a compound is formed containing not more than 15 per cent. of phosphorus: it has the colour of lead; may be cut with a knife, but splits into laminæ when hammered; tarnishes quickly when exposed to the air; and, when heated before the blowpipe, yields a phosphorus-flame and a globule of lead (Pelletier, Ann. Ch. Phys. [2], xiii. 114).—*b.* Phosphoretted hydrogen gas passed for two hours through a solution of neutral acetate of lead, yields a brown precipitate, which burns before the blowpipe with a small phosphorus-flame, forming beautifully crystallised lead-phosphate. (H. Rose, Pogg. Ann. xxiv. 326.)

LEAD, SELENIDE OF. Very small quantities of selenium combined with lead render it harder and less fusible.

The *protoselenide*, PbSe, is formed when lead and selenium are heated together, combination then taking place attended with incandescence, and a grey porous mass being formed, which becomes silver-white by polishing. When ignited in an open vessel, it first gives off selenium, then a small quantity of selenide of lead in white fumes, leaving a residue of basic selenite of lead. Cold nitric acid dissolves the lead, leaving red selenium, which, on heating the liquid, dissolves in the form of selenious acid. (Berzelius.)

Selenide of lead also occurs native, as clausthalite, sometimes pure, sometimes having part of the lead replaced by other metals, as cobalt, copper, mercury, and silver. It is found in fine-grained masses, sometimes foliated, with cubic cleavage. Hardness = 2·5 to 3. Specific gravity = 7 to 8·8. Lustre metallic. Colour lead-grey, sometimes bluish; cupreous varieties yellowish. Streak darker. Opaque. Fracture granular and shining. Rather sectile. Before the blowpipe it emits the odour of horse-radish and exhibits various other reactions characteristic of selenium (*q. v.*). Heated in a tube it yields a sublimate of selenium.

The following are analyses of clausthalite and its varieties:—*a*, H. Rose (Pogg. Ann. ii. 416; iii. 281); *b*, Stromeyer (*ibid.* ii. 403); *c*, Selenide of lead and silver (Rammelsberg, *Mineralchemie*, p. 34); *d*, Selenide of lead and cobalt; *e*, *f*, Selenides of lead and copper (H. Rose, Pogg. Ann. iii. 288); *g*, *h*, The same (Kersten, *ibid.* xlvi. 265):

Digitized by Google

The varieties *e*, *f*, *g*, *h*, which contain copper, are by some mineralogists rega distinct species; but it is perhaps better to regard them as varieties of claustha which part of the lead is replaced by copper; *e* and *f* are called *raphanos* Kobell; *d* is called *Tilkerodite* by Haidinger; *d*, *e*, and *f* are called *Zorgite* by and Miller; *e* and *h* agree nearly with the formula $\left.\begin{matrix}\frac{1}{2}\mathrm{Pb}\\ \frac{1}{2}\mathrm{Cu}\end{matrix}\right\}\mathrm{Se}$; *f* and *g* with $\left.\begin{matrix}\frac{3}{5}\mathrm{Pb}\\ \frac{2}{5}\mathrm{Cu}\end{matrix}\right\}$

Clausthalite and its varieties occur at Harzgerode, in the Hartz, and at Cl Tilkerode, Zorge, Glasbach, near Hildburghausen, and Lehrbach; also at Ra and Freiberg in Saxony.

Lehrbachite, which is a selenide of lead and mercury, and is described as hav structure and colour of clausthalite, is, perhaps, a mechanical mixture of that with selenide of mercury. It emits the odour of selenium before the blowpi gives mercury with soda. H. Rose found in one specimen 24·97 per cent. se 55·84 lead, and 16·94 mercury (=97·75); in another, 27·98 selenium, 27·33 le 44·69 mercury (=100).

LEAD, SULPHIDES OF. There are four compounds of lead and s namely, the protosulphide, two subsulphides, and a persulphide; but the protos is the only one whose constitution is accurately known.

Tetartosulphide. Pb^4S?—A finely divided mixture of 100 pts. of galena of lead heated for a quarter of an hour in a well-closed charcoal-lined crucible, in a wind-furnace with a strong draught, yields 144 pts. of a dull, lead-co fine-grained, semi-malleable, soft mixture, exhibiting a dark-grey colour on surface. When oxidised by nitric acid, it yields 36 per cent. of lead-sulpha must therefore contain 3·96 per cent. of sulphur. (Bredberg, Pogg. Ann. xvi

Hemisulphide. Pb^2S.—1. By the same process as for the preceding comp excepting that the mixture is fused in an earthen instead of a charcoal-lined c and covered with borax—150 pts. of a more brittle mixture are obtained, h dark leaden-grey colour, a finely laminar fracture, and containing 7·207 per sulphur (Bredberg).—2. Sulphate of lead ignited in a charcoal-lined crucibl off sulphurous anhydride and leaves hemisulphide of lead, which at a higher te ture, partly volatilises and is partly decomposed, leaving a residue of metall (Berthier, Ann. Ch. Phys. [2] xxii. 240.)

Protosulphide. PbS.—This compound is found native as galena (*bl galène*, *Bleiglanz*), the most abundant and important ore of lead. It occu quently in very fine crystals belonging to the monometric system, with cleavage, perfect and easily obtained. The ordinary forms are the octahedron and rhombic dodecahedron, occurring alone or in combination with other forms, example, subordinate; twins like *fig.* 320 (ii. 160), and others in which the ir ting cubes are of different sizes, or in which the diagonals do not exactly co also pseudomorphs after pyromorphite. The crystals are frequently imbedded, or u granular aggregations. The mineral likewise occurs in tabular, reniform or bot masses, coarse or fine granular, sometimes impalpable, occasionally fibrous. H = 2·5. Specific gravity = 7·25 to 7·7. Lustre metallic. Colour and strea lead-grey; surface of crystals occasionally tarnished. Fracture scarcely perc in the crystals, on account of the perfect cleavage; in the massive varieties, fl conchoïdal, or uneven. Before the blowpipe, it decrepitates strongly, melts and a globule of lead as soon as the sulphur is volatilised.

For analyses of galena, see p. 480.

Galena is found abundantly in England and in many parts of Europe; in the I Mountains, Siberia; in Algeria; near the Cape of Good Hope; in Australia; many parts of North America. It occurs in beds and veins, both in crystalli uncrystalline rocks, often associated with blende, iron and copper pyrites, ca of lead and other lead ores, and in a gangue of heavy spar, calcspar or quar often suffers decomposition, and gives rise to the formation of other plumb minerals.

Breithaupt's antimonial galena from Freiburg in the Breisgrau, with s gravity = 6·9 to 7·0, is perhaps the same as steinmannite from Przibram hemia. Whether the tetragonal galena of the same mineralogist, also cont antimony, is a dimetric variety of galena, is not exactly known.

Protosulphide of lead is produced artificially:—1. When sulphur is mixe melted lead, the whole becoming red-hot. Strips of lead even of moderate thi take fire in sulphur-vapour, and burn with vivid glow, depositing half-fused gl of the protosulphide.—2. By heating the protoxide with excess of sulphur.—3. action of sulphydric acid or an alkaline sulphide on the oxide or salts of l 4. Becquerel, by immersing cinnabar in a solution of chloride of magnesium contain glass tube, dipping a lead plate to the bottom, and leaving the tube well closed

Digitized by Google

weeks, obtained grey, metallic-shining, regular tetahedrons of the protosulphide, which formed on the sides of the tube.

Sulphide of lead obtained by fusing its elements together is of a lead-grey colour, with granular fracture; that which is precipitated by sulphydric acid is a brown-black powder, and, according to Karsten, has a density of 7·5052 after fusion. Sulphide of lead melts at a strong red heat, volatilises at a stronger heat, and sublimes undecomposed if kept from contact with the air.

Decomposition.—1. Sulphide of lead, when gently ignited in the air, gives off the greater part of its sulphur in the form of sulphurous anhydride, while metallic lead (amounting to about half the total quantity) and sulphate of lead remain behind (Descotils, Ann. Ch. Phys. [2] lv. 441).—2. The protosulphide and protoxide of lead decompose one another when heated together, evolving sulphurous anhydride and leaving metallic lead:

$$PbS + 2PbO = Pb^3 + SO^2.$$

—3. The protosulphide heated in vapour of water gives off sulphydric acid and yields metallic lead. The first products formed are sulphydric acid and the protoxide, which then reacts on the remaining sulphide in the manner just described.—4. When sulphide of lead is fused with alkaline carbonates, half the lead is separated in the metallic state, and on addition of metallic iron, the whole.

Protosulphide of lead is insoluble in *dilute acids*, in caustic *alkalis*, and *alkaline sulphides*. When boiled with *dilute nitric acid* it gradually dissolves as nitrate, with evolution of nitric oxide, and separation of sulphur. The finely divided sulphide treated with *fuming nitric acid* is completely converted into sulphate of lead: but if any portion of the sulphur remains unoxidised, a corresponding quantity of the lead is converted into nitrate. By strong *hydrochloric acid* it is converted into chloride of lead with evolution of sulphydric acid. *Nitro-hydrochloric acid* converts it into chloride and sulphate of lead. *Chlorine* decomposes it slowly, forming chloride of lead and chloride of sulphur.

Persulphide. A solution of a lead-salt mixed with pentasulphide of potassium yields a precipitate, which has at first a fine blood-red colour, but quickly loses this colour, even while immersed in the liquid, and is resolved into the protosulphide and free sulphur. Higher sulphides of lead are also said to be formed by the action of sulphydric acid on the sesquioxide and peroxide of lead; but their composition has not been made out.

LEAD, SULPHOCARBONATE OF. See SULPHOCARBONATES.

LEAD, SULPHOCHLORIDE OF. If a lead-salt, *e.g.* aqueous chloride of lead, be precipitated by a mixture of aqueous sulphydric and hydrochloric acids, there is produced, first a yellowish-red, and then a red precipitate containing about 56 per cent. (3 at.) of lead-sulphide, and agreeing very nearly with the formula, $PbCl^2.3PbS$. An excess of sulphydric acid turns it black and converts it into pure sulphide of lead; the same change is produced by boiling with water, which extracts the chloride; the compound is also blackened by potash, which extracts the chlorine (Hünefeld, J. pr. Chem. vii. 27).—When sulphydric acid gas is passed through a solution of ½ pt. lead-acetate in 100 pts. of water mixed with 10 pts. of hydrochloric acid of specific gravity 1·168, a beautiful carmine-coloured precipitate of sulphochloride of lead is produced If the solution contains 1 pt. of lead-acetate, 112 pts. of water, and 14 of strong hydrochloric acid, sulphydric acid produces a yellow precipitate, which gives up chloride of lead to boiling water, while black protosulphide of lead remains behind. If, instead of 14 pts. of strong hydrochloric acid, we use 14 pts. of a mixture of 2 pts. of strong hydrochloric and 1 pt. nitric acid, prepared two days before and containing pernitric oxide, the sulphydric acid produces, after a while, first a yellowish-red and then a cinnabar-red, granular precipitate. If the stream of sulphydric acid gas were continued for a longer time, the precipitate would become first carmine-coloured, then brown, and lastly black. The red granular precipitate, when boiled with water, gives up a considerable quantity of chloride of lead, and is converted into a brown-red, flocculent powder, which then undergoes no further change, but when heated alone in a glass tube, gives off sulphur and sulphydric acid, and fuses to a brown mass. According to this reaction, the pernitric oxide must have precipitated sulphur from the sulphydric acid, and the red precipitate is a compound of the chloride with a polysulphide of lead. (Reinsch, J. pr. Chem. xiii. 130.)

LEAD, SULPHOCYANATE OF. See SULPHOCYANATES.

LEAD, WHITE. Hydrated carbonate of lead used as a pigment (ii. 786). The native anhydrous carbonate is also called white lead ore.

LEAD-GLANCE. Syn. with galena (see p. 558).

Digitized by Google

LEAD-GLASS. *Vitrum plumbi.*—A term formerly applied to perf
oxide of lead. Oxide of lead is used as an ingredient in various kinds of g
flint-glass, crystal-glass, strass, &c. (ii. 841).

LEAD-GLAZE. The glaze of the more common kinds of earthenware
an easily fusible silicate of lead, prepared from a mixture of finely ground
litharge, white lead, or galena, with clay or sand. It melts more easily in
as it is richer in lead, but when the proportion of lead is very large, the glaz
posed by dilute acids, which dissolve part of the oxide of lead.

LEADHILLITE. *Sulphato-tricarbonate of lead,* $PbSO^4.3PbCO^3$ =

—A crystallised mineral occurring, together with other ores of lead, at L
Scotland; said also to be found in Grenada, in the island of Serpho, Greci
pelago, and in the Newberg district, South Carolina. The crystals are
exhibiting the planes $\infty\breve{P}\infty$ (greatly predominant), $\infty\breve{P}\infty$, ∞P, $\frac{4}{3}\breve{P}\infty$, $\frac{4}{3}$
$\frac{1}{3}$ P and others. Angle $\infty P : \infty P = 103° 16'$. Ratio of principal axi
diagonal and macrodiagonal = 1·7205 : 1 : 1·2632. The crystals are
in ∞P and some other planes; hence they are monoclinic in aspect, or rho
when in compound crystals. Cleavage very perfect parallel, to $\infty\breve{P}\infty$; in trac
to $\infty\breve{P}\infty$. Twins consisting of three crystals, with face of composition $\breve{P}\infty$;
lel to ∞P. Hardness = 2·5. Specific gravity = 6·2—6·5. Lustre of $\infty\breve{P}\infty$
the other faces resinous, somewhat adamantine. Colour white, passing in
green, and grey. Streak uncoloured. Transparent to translucent. Conch
ture scarcely observable. Rather sectile. Before the blowpipe, it intumesc
then turns yellow, but becomes white on cooling; easily reduced on cha
effervesces briskly in nitric acid, and leaves a white residue of lead-sulphate
Berzelius found in the mineral 28·7 per cent. sulphate, and 71·0 carbona
(= 99·7); Stromeyer found 28·3 sulphate, and 72·7 carbonate (= 100); th
requires 27·44 sulphate and 72·56 carbonate. (Dana, ii. 371.)

LEAD-MATT. *Matte de plombe. Bleistein.*—This term is applied t
tures of sulphide of lead with other metallic sulphides, chiefly sulphide of iron
in the metallurgic treatment of lead-ores (p. 492).

LEAD-OCHRE. Native protoxide of lead (p. 550).

LEAD-PLASTER. A mixture of the lead-soaps of fatty acids, used
cine as an external application. It is prepared by heating 9 pts. o
(sometimes also lard or rape-oil) nearly to its boiling-point, then adding
5 pts. of powdered litharge, incorporating thoroughly with a spatula, ad
time to time small portions of warm water, and continuing the heating
poration till a few drops of the mixture harden when thrown into water, a
glutinous mass between the fingers. Sometimes a mixture of litharge and
is used instead of litharge alone.—Well-prepared lead-plaster forms a whit
homogeneous mass, somewhat flexible and tenacious in summer, brittle in wint
gently heated, it melts to a thick liquid, which, at higher temperatures, tur
and finally black, giving off irritating vapours.

LEAD-RADICLES, ORGANIC. These compounds, the series of w
present far from complete, are obtained by the action of the iodides of th
radicles on lead or its alloys with potassium or sodium, or of zinc-ethyl on
lead. The formation of ethyl-compounds by the first of these processes
observed in 1853 by Löwig (J. pr. Chem. lx. 304; Ann. Ch. Pharm lxxx
soon afterwards by Cahours and Riche. (Compt. rend. xxxvi. 1002.)
The iodide of the radicle $Pb^2(C^2H^5)^6$ was discovered by Löwig, who desig
radicle methplumbethyl, and studied several of its compounds, but did
it in the free state. It has since been isolated (1860) by Klippel (J.
lxxxi. 287), who has likewise obtained the corresponding amyl-compou
compound $Pb(C^2H^5)^4$ was discovered in 1858 by Buckton (Phil. Mag.
212, xvii. 282; Ann. Ch. Pharm. cix. 218, cxii. 220); and the corr
methyl-compound by Cahours in 1861 (Ann. Ch. Phys. [3] lxii. 257;
Pharm. cxxii. 48), who likewise obtained by its decomposition, the
$Pb^2(CH^3)^6$.

Amyl-compounds.

Plumbotriamyl. *Methplumbamyl.* $Pb^2(C^5H^{11})^6 = Pb^2Am^6$.—Prepared
corresponding ethyl-compound) by distilling an alloy of lead and sodium w
of amyl. shaking up the distillate with ether, distilling off the ether after a

Digitized by Google

a little alcohol, and treating the residue with a large quantity of water. Plumbotriamyl then separates as a yellowish, oily, non-volatile liquid, inodorous in the cold, smelling like plumbotriethyl when warm: its vapour exerts an irritating action on the mucous membranes. When set on fire it burns, with separation of lead-oxide. With fuming nitric acid it detonates, with emission of light and heat.

The *chloride*, $PbAm^3Cl$, is obtained by treating the oxide (*infra*) with hydrochloric acid. It crystallises in white needles.

The *iodide*, $PbAm^3I$, is obtained in white needles by adding iodine to the ethereal solution of plumbotriamyl, till the colour becomes permanent, and evaporating the filtrate. It is more stable than the corresponding ethyl-compound, melting at 100° without decomposition, and solidifying in the crystalline form on cooling. It is insoluble in water. It unites with *mercuric iodide*, forming the double salt $PbAm^3I.HgI^2$, which crystallises in golden-yellow laminæ, insoluble in water, sparingly soluble in alcohol and ether.

Oxide.—By agitating the alcoholic solution of the iodide with recently precipitated oxide of silver, evaporating the filtrate, and treating the residue with water, oxide of plumbotriamyl separates as a faintly yellow viscid mass, insoluble in water, soluble in alcohol and ether; the alcoholic solution has a faint alkaline reaction, and precipitates ferric salts, but not copper or silver salts.

The *sulphate*, obtained by heating the oxide with dilute sulphuric acid, is a viscid uncrystallisable mass. (Klippel.)

Ethyl-compounds.

Plumbotriethyl. $Pb^2(C^2H^5)^6 = Pb^2E^6$. Löwig's *Methplumbethyl.*—Löwig, by acting on an alloy of 6 pts. lead and 1 pt. sodium with iodide of ethyl, obtained a mixture of several lead-compounds of ethyl, which he was not able to separate. The mixture was perfectly colourless, tolerably mobile, volatile, and had a powerful odour; did not fume in the air, but when set on fire burnt and gave off dense clouds of oxide of lead. It took fire when strong nitric acid was poured upon it, and exploded with great violence in contact with iodine or bromine. It was insoluble in water, but dissolved readily in alcohol or ether; and the solutions, when exposed to the air, deposited an amorphous powder, insoluble in water, alcohol and ether, but capable of forming crystallisable salts with acids, while in solution there remained a strongly alkaline base, the oxide of plumbotriethyl, the radicle of which appeared to constitute the greater part of the product. This radicle, however, Löwig did not succeed in isolating.

Klippel prepares an alloy of lead and sodium, having nearly the composition Pb^2Na^2, by melting 3 pts. of lead in a hessian crucible, and after removing it from the fire, adding 1 pt. sodium in small pieces still moistened with rock-oil, and stirring with an iron rod. Combination then takes place, attended with evolution of heat and inflammation of the rock-oil (the gases evolved by which protect the alloy from oxidation). When the action is completed, the crucible is filled with warm sand and left to cool slowly; the crystalline alloy is pulverised in a warm mortar, with addition of a small quantity of dry sand, then introduced into a number of small flasks and drenched with iodide of ethyl, and the flasks are immediately connected with a condensing tube, to prevent loss of iodide of ethyl, which distils over in consequence of the heat evolved by the violent action which immediately takes place. The iodide of ethyl is allowed to flow back into the flasks as long as any action goes on, and when it is completed the excess of iodide of ethyl is distilled off over the water-bath; the remaining liquid is poured out of the flasks into a dry glass cylinder and shaken up with ether, which dissolves the plumbotriethyl; and the ether is distilled off after addition of a little water: the plumbotriethyl then separates as an oil at the bottom of the water.

Plumbotriethyl is a yellowish mobile oil, of specific gravity 1·471 at 0°, insoluble in *water*, easily soluble in *alcohol* and *ether*. It volatilises undecomposed in small quantity with ether-vapour, but cannot be distilled alone. By the action of light, or by prolonged boiling with water, it decomposes, with separation of metallic lead (Klippel). When exposed to the air in ethereal solution, it is converted into oxide (Löwig), carbonate (Klippel). *Chlorine-water* decomposes it, with separation of chloride of lead. (Klippel.)

Bromide of plumbotriethyl, PbE^3Br, is obtained by adding an alcoholic solution of bromide of potassium to a solution of the sulphate in alcohol containing sulphuric acid, agitating the whole with ether, then with water to separate the ethereal solution, and evaporating the ether; it then crystallises in long needles. (Löwig.)

The *chloride*, PbE^3Cl, is obtained by adding chloride of barium to a solution of the sulphate in alcohol containing hydrochloric acid, agitating with ether, separating the ethereal solution by water, and leaving it to evaporate (Löwig); by neutralising

Digitized by Google

the oxide or carbonate with hydrochloric acid (Klippel); or by the action of chloric acid gas on plumbotetrethyl (Buckton, p. 563). It crystallises in b long needles, having a high lustre, and giving off a strong odour of oil of when gently heated. When heated in a glass tube, they detonate slightly, e moderate heat, yielding chloride of lead and metallic lead. (Löwig.)

The *chloromercurate*, $PbE^3Cl.HgCl^2$, separates from a hot alcoholic sol the component salts in white nacreous scales; the *chloroplatinate*, $2PbE^3C$ in copper-red crystals, sparingly soluble in water, more easily in alcohol an (Klippel.)

The *cyanide*, $C^7H^{15}NPb = PbE^3Cy$, is obtained by heating cyanide of po with an alcoholic solution of chloride of plumbotriethyl, for a considerable ti sealed tube placed in a water-bath, mixing the resulting blood-red liquid wit and recrystallising the resulting white precipitate from ether. It then sepa prismatic crystals, which, when heated in a tube, melt and decompose, with defla separation of metallic lead, and evolution of inflammable vapours. (Klippe

The *iodide*, PbE^3I, formed by the action of iodine on plumbotriethyl (Kl or by the reaction of iodide of potassium and sulphate of plumbotriethyl (Lö soluble in ether and very unstable, the ethereal solution quickly yielding a de iodide of lead.—If the compound, while yet undecomposed, be distilled with wate of lead separates immediately, and the water which passes over is accompan colourless, mobile, very pungent liquid, no longer prone to spontaneous decomp and having nearly the composition $(PbE^3)^4I^3$. (Löwig.)

Oxide of plumbotriethyl is obtained in the hydrated state by adding a of nitrate of silver mixed with alcohol to the alcoholic solution of the mixed as long as metallic silver is precipitated; filtering from the silver; agitating th ing solution of nitrate of plumbotriethyl with alcoholic potash and afterwards wit adding a sufficient quantity of water to separate the ethereal solution of the oxi evaporating the ether in a retort. Hydrated oxide of plumbotriethyl then re the form of a thick oily liquid, which solidifies after a while in a crystalli slippery to the touch, like hydrate of potassium (Löwig). It may also be prep gradually adding iodine to the ethereal solution of plumbotriethyl till the c longer disappears, and immediately agitating the liquid with moist oxide of sil alkaline solution is thus obtained which, on addition of water and remova alcohol and ether by distillation, deposits hydrate of plumbotriethyl as a nearly co thickish oil (Klippel). It is volatile, and forms white fumes when a rod m with hydrochloric acid is held over it. When heated, it gives off white vapour excite powerful sneezing—a property which also belongs to the radicle itself an of its compounds. The hydrate dissolves sparingly in water, readily in alcoho ether; has a strong alkaline reaction, and a sharp, disagreeable, caustic taste (Klippel); saponifies fats; precipitates the oxides of iron, copper and silver fr salts; also alumina and oxide of zinc, both of which it redissolves when a excess. (Klippel.)

Oxygen-salts. The oxide unites readily with acids, forming crystallisable

The *acetate*, *benzoate*, and *butyrate* form needle-shaped crystals, soluble in alcohol, and ether.

Carbonate, $Pb^2E^6CO^3$.—The hydrated oxide rapidly absorbs carbonic ac the air, and by leaving the alcoholic solution to evaporate in the air, the carb obtained in small hard crystals (Löwig); or it may be prepared by passing anhydride into the solution, and separated by addition of carbonate of ammo being taken however to avoid an excess of the latter, which would give rise to th tion of an easily soluble double salt. Carbonate of plumbotriethyl has a strong taste, is nearly insoluble in water, sparingly soluble in alcohol and ether. containing hydrochloric acid dissolves it with effervescence. (Löwig.)

Formate of plumbotriethyl resembles the acetate.

The *nitrate*, PbE^3NO^3, is obtained by decomposing the alcoholic solution mixed plumbethyls (Löwig, p. 561), or the ethereal solution of pure plumb (Klippel) with nitrate of silver. It remains on evaporation as a colourles liquid, which smells like butter, has a burning taste, and solidifies after a wh crystalline unctuous mass. It is decomposed by heat, with slight detonat dissolves readily in alcohol and ether; the alcoholic solution when evaporated, a small quantity of nitrate of lead. (Löwig.)

The neutral *oxalate* forms scaly laminar crystals, which when dried over oil o contain $C^2(PbE^3)^2O^4.H^2O$. (Klippel.)

A *phosphate* $(PbE^3)H^2PO^4$, is obtained, by saturating the oxide or carbon phosphoric acid, in stellate groups of crystals which dissolve readily in water, and ether, and are oxidised with vivid deflagration, when treated in the dry st fuming nitric acid. (Klippel.)

Digitized by Google

Sulphate. $(PbE^2)^2SO^4$.—When sulphuric acid is added by drops to an alcoholic solution of the oxide, leaving the base in excess, a dazzling white crystalline precipitate of the sulphate is obtained, which must be washed with alcohol and afterwards with ether. The salt is nearly insoluble in water, absolute alcohol, and ether, but dissolves readily in alcohol mixed with sulphuric or hydrochloric acid. From the acid solution it crystallises in tolerably large, hard, shining octahedral crystals (Löwig). Klippel, by dissolving the carbonate in alcoholic sulphuric acid, obtained the sulphate in crystals like those of quartz. Buckton, by decomposing the chloride with sulphuric acid or sulphate of silver, obtained it in asbestiform needles.

The *acid tartrate*, $C^4H^4(PbE^2)O^6$ (at 100°), forms scaly laminar crystals.

Sulphide of plumbotriethyl is obtained by treating a solution of the oxide or a salt of plumbotriethyl, with sulphydric acid or sulphide of ammonium, as a white precipitate, which is nearly insoluble in water, alcohol, and ether, and blackens quickly with separation of sulphide of lead. (Klippel.)

The *sulphocyanate* is formed by heating an alcoholic solution of the chloride with recently precipitated sulphocyanate of silver to 100° in a sealed tube. It dissolves in water, alcohol, and ether, and crystallises from the ethereal solution in the same form as sulphocyanate of potassium. (Klippel.)

Plumbotetrethyl. $Pb^2C^8H^{20} = Pb(C^2H^5)^4$ or PbE^4. *Diethylide of lead. Plumbodiethylide* (Buckton).—Produced by the action of zinc-ethyl on chloride of lead:

$$2ZnE^2 + 2PbCl^2 = 2ZnCl^2 + PbE^4 + Pb.$$

When dry chloride of lead is added to zinc-ethyl, decomposition takes place immediately, attended with separation of metallic lead, and slight rise of temperature; and on adding an excess of the lead-chloride, and warming gently for a few minutes, a clear liquid may be decanted, apparently consisting of several lead-radicles combined with zinc-ethyl, which cannot be completely removed by digestion with excess of lead-chloride, but may be expelled for the most part by distillation. The liquid remaining in the retort at 140°-150° yields, when treated with water and hydrochloric acid, heavy colourless drops of a liquid, the greater part of which, consisting of plumbotetrethyl, distils over between 198° and 202°; but the compound is most easily obtained in the pure state by distillation in a rarefied atmosphere. (Buckton.)

Plumbotetrethyl is a transparent colourless liquid of specific gravity 1·62. Under the ordinary pressure it boils with partial decomposition, at a few degrees above 200°, but under a pressure of 7·5 inches of mercury it boils without decomposition at 152°. When set on fire, it burns with pale-green-bordered flame, emitting a fume of lead-oxide. In a stream of hydrochloric acid gas, it is converted into chloride of plumbotriethyl, with evolution of hydride of ethyl:

$$Pb(C^2H^5)^4 + HCl = Pb(C^2H^5)^3Cl + C^2H^6.H. \quad \text{(Buckton.)}$$

Methyl-compounds.

Plumbotrimethyl. $PbC^3H^9 = Pb(CH^3)^3 = PbMe^3$.—This radicle has not yet been obtained in the free state, but its salts are produced, with evolution of hydride of methyl, by treating plumbotetramethyl with acids: *e.g.* with hydrochloric acid, the reaction being precisely similar to that which takes place in the case of the corresponding ethyl compound, as represented by the equation just given.

Chloride of plumbotrimethyl, $PbMe^3Cl$, thus obtained, separates from the solution on cooling in long needles very much like chloride of lead. If the boiling of the plumbotetramethyl with hydrochloric acid be too long continued, chloride of lead is apt to be formed.

Bromide of Plumbotrimethyl is somewhat more soluble than the chloride.

The *iodide*, $PbMe^3I$, is obtained by adding iodine to plumbotetramethyl till the colour becomes permanent (iodide of methyl being probably formed at the same time:

$$PbMe^4 + I^2 = PbMe^3I + MeI).$$

The product is a white solid mass, mixed with yellow iodide of lead, sparingly soluble in water, easily in alcohol, and crystallising in long colourless needles, which may be sublimed. By distillation with caustic potash, it yields the hydrate of plumbotrimethyl, as a strong basic oil, smelling like oil of mustard, and solidifying in prismatic needles. (Cahours.)

Plumbotetramethyl. $PbC^4H^{12} = Pb(CH^3)^4 = PbMe^4$.—Produced by the action of iodide of methyl on an alloy of 5 pts. lead and 1 pt. sodium, or, better, by treating chloride of lead with zinc-methyl. It is a colourless, mobile liquid, having a camphor-like odour, insoluble in water, but soluble in alcohol and ether. It boils at 160°, decomposes at a few degrees above that temperature, but may be distilled with-

Digitized by Google

out alteration in a gas which does not act upon it (Cahours). Accord Buttlerow, however, it smells like strawberries or mould, not at all like ca boils at 100°,* and when free from zinc-methyl, may be distilled without de sition in contact with air; in a sealed tube containing chlorocarbonate of ethyl, be heated to 200° without decomposition. Its vapour-density, determined Lussac's method, is 9·66 at 115°, and 9·52 at 130°; calculation = 9·25. It then that the compound is converted into a perfect gas at a temperature ve above its boiling point. (Buttlerow.)

Plumbotetramethyl, like the corresponding ethyl-compound, does not unite with *oxygen*, *chlorine*, or *iodine*, but is decomposed thereby, yielding compo which part of the methyl is replaced by the acting elements, but belonging to t type as plumbotetramethyl itself; *e.g.* iodide of plumbotriethyl, $Pb(CH^3)^3I$, action of iodine. Treated with *acids*, it yields hydride of methyl and a salt of triethyl. (Cahours.)

LEAD-SOAPS. Lead-salts of the fat-acids. Common lead-plaster (p. a preparation of this kind.—Palmer in 1845 patented the preparation of a le for greasing the axles of railway carriages, &c. It is prepared by heating the oleic acid obtained from the manufacture of stearin-candles, and stirring litha it as long as the litharge is dissolved. Before use it is mixed with a certain quanti or tallow.—A compound of lead-oxide with the acids of linseed-oil, prepared by de ing the potash-soap of linseed-oil with solution of acetate of lead, serves, when d in oil of turpentine, for printing on wall-paper, previous to gilding it with gold Dutch metal, or dusting it with wool-shearings for the production of flock-patt

LEAD-SPEISS. The metallurgical name of certain products obtained working of lead-ores containing arsenic or antimony. The following table the composition of two lead-speisses analysed by Bodemann: *a*, from Claus from Andreasberg, and another; *c*, by Ahrend from the Lower Hartz:

LEAD-VITRIOL. Sulphate of lead (see SULPHATES).

LEAF-GREEN. See CHLOROPHYLL (i. 922).

LEAF-RED. See ERYTHROPHYLL (ii. 506).

LEAF-YELLOW. See XANTHOPHYLL.

LEATHER consists of the skins of animals prepared by a process, or rath of processes, called tanning, by which they are preserved from putrefyin moist, and rendered soft and pliable when dry. The skins are first freed from mis, fatty matter and hairs, by steeping them in milk of lime, or in an acesc fusion of barley- or rye-meal, or spent tan, which sets up a slow fermentat either of these modes of treatment, the epidermis and the cellular tissue in wh hairs are rooted, are disintegrated, so that the hair and epidermis can then b removed by scraping. The skins thus prepared are then steeped in an infusion substance capable of uniting with the true skin and converting it into leathe materials used for this purpose are:

1. *Tannin* or *tannic acid*, in the process of tanning properly so called, w applied chiefly to the stouter kinds of leather, made from the hides of oxen and The true skin of animals is a gelatinous tissue (ii. 826) and gelatin unit tannic acid, forming a tough insoluble substance possessing the properties of (ii. 765). Several substances are used by the tanner as sources of tannic acid; most valuable and most extensively used of all is oak-bark. The followi stances are also used, sometimes alone, but more generally as additions to the oa —Sumach, from the bark of *Rhus cotinus* or *Rhus coriaria*; catechu, or *Terr nica*, chiefly from various species of *Acacia* (i. 816); dividivi, the crushed *Cæsalpinia coriaria*; mimosa, from the bark and pods of various kinds of *Pro* genus of leguminous plants; valonia, the acorn of the great prickly-cupp (*Quercus Ægilops*); and nut-galls.

2. *Alum* and *common salt*, in the process called tawing, which is applied to the lighter kinds of skin, namely these of sheep, goats, and calves.

* This boiling point differs from that of plumbotetrethyl (about 200°) by 90°, or 22·5° for a diff CH^2 in the formulæ, whereas the boiling point of plumbotetramethyl found by Cahours, viz. 160 from 200 by only 40°, or by 10° for each difference of CH^2 in the formulæ. Now on comparing ferences of boiling points in the corresponding methyl- and ethyl-compounds of phosphorus, arse mony, and tin, it is found that the difference always amounts to 20° or upwards for each molecul added to the compound. The boiling point of plumbotetramethyl found by Buttlerow is theref in accordance with analogy than that determined by Cahours.

3. *Oil*, for the preparation of chamois, shamoy, or wash-leather, which is prepared from the skins of the goat, doe, or chamois, and is a soft, spongy leather, capable of washing.

4. *Lime*, for parchment, which is prepared from calf or sheep skins, and for the stronger kinds, from asses' or pig's skin.

For the details of all these processes we must refer to *Ure's Dictionary of Arts, &c.* (ii. 674—686), and the *Handwörterbuch der Chemie* (iv. 792—810).

LECANORIC ACID. $C^{16}H^{14}O^7$? *Lecanorin. α-Orsellic acid.* (Schunck, Ann. Ch. Pharm. xli. 157; liv. 261; lxi. 72.—Rochleder and Heldt, *ibid.* lxviii. 1. —Stenhouse, *ibid.* lxviii. 61; lxx. 218.—Strecker, *ibid.* lxviii. 13.—Laurent and Gerhardt, Ann. Ch. Phys. [3], xxiv. 315.—Robiquet, Ann. Ch. Phys. xlii. 236; Gm. xii. 377.)—This substance, which was discovered by Schunck in 1842, is extracted from several lichens belonging to the genera *Lecanora* and *Variolaria*. The lichens, in the state of fine powder, are exhausted with ether in a percolator, and, on evaporating the ether, a residue is obtained which is to be washed with ether on a large funnel till it is colourless, then exhausted with water, and crystallised from alcohol (Schunck). Rochleder and Heldt exhaust the lichen (*Evernia prunastri*) with a mixture of ammonia and alcohol, dilute the alcohol with a third of its volume of water, and saturate with acetic acid. Lecanoric acid then separates in grey flocks, which are washed, dried at 100°, dissolved in a small quantity of boiling absolute alcohol, and purified by recrystallisation.

Stenhouse macerates the lichen (*Roccella tinctoria*) with water mixed with slaked lime, precipitates the filtered liquid with hydrochloric acid; washes and dries the gelatinous precipitate, and digests it, when nearly dry, with absolute alcohol, taking care not to boil the liquid, which, on cooling, deposits the acid in crystals.

Lecanoric acid crystallises in colourless stellate needles, sparingly soluble in cold *water* and in cold *alcohol;* moderately soluble in boiling alcohol, soluble in *ether* and in *acetic acid*. According to Schunck, 1 pt. of lecanoric acid requires for solution 2,500 pts. of boiling water, 150 pts. of alcohol of 80 per cent. at 15°; 5·15 pts. of boiling alcohol, and 80 pts. ether at 15·5°. The solution reddens litmus. The crystallised acid does not lose weight at 100°.

Lecanoric acid gives by analysis 59·45 to 60·59 carbon, and 4·40 to 5·00 hydrogen, whence Stenhouse deduced the formula $C^{16}H^{14}O^7$, which Gerhardt altered to $C^{18}H^{14}O^7$ (60·37 per cent. C, 4·40 H, and 35·23). This latter formula readily explains the conversion of lecanoric into orsellic acid (*infra*).

Lecanoric acid yields by dry distillation, a viscid oil, together with orcin. It dissolves readily at ordinary temperatures in lime-water or baryta-water, and is precipitated therefrom by acids in the form of a jelly, and without alteration; but if the saturated solution be boiled, the lecanorate of barium or calcium changes into the much more soluble *orsellinate*. If the ebullition be prolonged, carbonate of barium or calcium is precipitated, and *orcin* remains in solution:

$$\underset{\text{Lecanoric acid.}}{C^{16}H^{14}O^7} + H^2O = \underset{\text{Orsellinic acid.}}{2C^8H^8O^4} = 2CO^2 + \underset{\text{Orcin.}}{2C^7H^8O^2}.$$

A solution of lecanoric acid in aqueous *ammonia* acquires by exposure to the air a fine purple colour, due to the formation of orcein. In contact with *hypochlorite of calcium*, lecanoric acid immediately assumes a red tint, quickly changing to brown and yellow. The acid heated with *sulphuric acid*, is gradually converted into orcin. Boiling *nitric acid* converts it into oxalic acid. Boiling *acetic acid* dissolves it readily, and deposits it in small needles on cooling. By boiling with *alcohol*, it is converted into orsellate of ethyl. The same change is produced by passing hydrochloric acid gas into a solution of lecanoric acid in absolute alcohol, saturated at the boiling heat.

The ammoniacal solution of lecanoric acid forms white precipitates with basic *acetate of lead* and *nitrate of silver*: but the silver precipitate is quickly reduced. The alcoholic solution gradually produces, with an alcoholic solution of *acetate of copper*, a light apple-green precipitate. It does not precipitate the alcoholic solutions of neutral acetate of lead, mercuric chloride, chloride of gold or nitrate of silver. A few drops of *ferric chloride* impart to it a deep purple colour.

The lecanorates gradually decompose, especially when heated, yielding orsellinic acid, and ultimately orcin. The *barium-salt*, $C^{16}H^{12}BaO$, is obtained by dissolving the acid in cold baryta-water, passing carbonic acid into the liquid, and treating the precipitate with alcohol, which dissolves the lecanorate of barium, and deposits it in small stellate needles. According to Stenhouse's analysis, it contains 49·27 per cent. C, 3·81 H, and 19·49 baryta; the formula requires 49·87 C, 3·37 H, and 19·73 baryta. The *calcium-salt* is a gelatinous precipitate, slightly soluble in water and alcohol, obtained by mixing an ammoniacal solution of the acid with chloride of calcium. The

Digitized by Google

lead-salt is precipitated, according to Rochleder and Heldt, on mixing the coholic solutions of lecanoric acid and acetate of lead; the precipitate thu probably consists for the most part of orsellinate.

LECANORIN. Syn. with LECANORIC ACID.

LECITHIN. Gobley's *Matière visqueuse.* (Gobley, J. Pharm. [3] 161; xi. 409; xii. 5; xvii. 401; xviii. 107; xix. 406; xxi. 241; xxx. 2 161.)—The eggs and milt or soft roe of the carp and herring, the yolk of po the brain of the domestic fowl, of man and of the sheep, venous blood, ox-bi fat of the garden-snail, contain, together with cholesterin, olein and m viscous substance which is decomposed by boiling with acidulated wate cerebrin, oleic acid, margaric acid and phosphoglyceric acid (ii. 891). Of thes Gobley regards the cerebrin as adventitious, the other three as resultin decomposition of a non-isolable substance, *lecithin*. The portion of pig's l in alcohol and not precipitable by ether contains, besides cholesterin and or a phosphoretted fat corresponding with Gobley's lecithin, and resolvable with baryta-water into phosphoglycerate of barium and insoluble b (Strecker, Ann. Ch. Pharm. cxxiii. 356). A constituent of yolk of egg, ear-wax, described by Kodweiss (Ann. Pharm. lix. 261), agrees also in pro the substance described by Gobley.

When carps' eggs are exhausted with ether or boiling alcohol, and the evaporated, there remains a reddish-yellow soft mass, which when redissolved alcohol, leaves a small quantity of oil. and separates again as a viscous mass It may also be obtained in the same manner, but less pure, from yolk of egg When the comminuted and partially dried milt of the carp is shaken up the ether takes up the greater part of the viscous matter, and the rest may be o repeated boiling with alcohol. On evaporating the alcoholic solution, trans viscous matter contained in the residue to ether by agitation therewith, and e the ether, the viscous matter is obtained free from the salts taken up by t which remain in the lower watery layer of liquid.

The viscous matter is colourless, or has merely a faint yellow or orange soft, neutral, and has for the most part the odour of the material from which prepared. It is frequently contaminated with earthy phosphates and It swells up when *heated*, chars without melting, gives off ammoniacal va leaves an acid carbonaceous residue containing phosphoric acid. When exp *air*, it does not turn acid, and afterwards yields the same decomposition-p that which has been prepared without exposure to the air. When shake *water*, it forms an emulsion which does not become sour or exhibit the p phosphoglyceric acid, even after 12 hours' boiling, but on boiling it with wat ing *sulphuric* or *hydrochloric acid*, oleic and margaric acids are formed, wh the surface as an oil, and phosphoglyceric acid, which remains dissolved in Addition of alcohol accelerates this decomposition, which, in viscous matter of egg, takes place at the mere heat of the water-bath, but in that derived f sources, not till after half an hour's actual boiling. The oxygen of the influence on the decomposition. Besides the products above mentioned, obtained cerebrin, and sometimes also cholesterin, olein and margarin, whic are regarded by Gobley as accidental admixtures.—Aqueous *alkalis* and *al bonates* at the boiling heat produce the same decomposition as the mineral aci the viscous matter of yolk of egg is shaken up with water containing potash in the water-bath, acetic acid separates oleic and margaric acids from it; with matter of the brain or from any other source, boiling with alcoholic potash is to effect the decomposition. Carbonate of potassium also does not deco viscous matter merely at the heat of the water-bath, but only on actual boi hours' boiling with *acetic* (lactic or tartaric) acid does not produce any deco 12 hours' boiling only an imperfect decomposition of the viscous matter; hours' boiling, it is completely decomposed, with formation of phosphoric glycerine. (Gobley.)

From the emulsion formed by *water*, which froths like soap (Gobley), it tated by common salt. (Kodweiss.)

The viscous matter dissolves sparingly in cold, easily in boiling *alcohol*, soluble in *ether*. (Gobley.)

LECONTITE. This name is given by W. H. Taylor (Sill. Am. J. 273) to an alkaline sulphate, found by Le Conte in the cavern of Las Pie Comayagua in Honduras, and probably formed from the excrements of b frequent the cavern in large numbers. The mineral, when freed from adheri matter, is colourless, permanent in the air, and has a saline, bitter forms prismatic crystals, which, according to Dana, are trimetric com

LEELITE. Syn. with HELLEFLINTA (p. 141).

LEGUMIN, or *Vegetable Casein,* was discovered by Einhof in 1805 called by him *végéto-animale* (N. allgem. J. d. Ch. v. A. Gehlen, vi. 126, found it in peas, beans, and lentils. A similar nitrogenised substance, extr sweet and bitter almonds and termed *amandin,* has been investigated b H. Vogel, Boullay, and others, who considered the substance in ques identical with animal casein. Braconnot, and afterwards Liebig, have the same result; they find, indeed, that legumin and casein are perfectl in composition and properties. Dumas and Cahours on the other hand, tained a substance containing less carbon and more nitrogen than casein sessing somewhat different properties. Their analyses agree very closely another, but it is highly probable that the substance analysed contained so body, perhaps arising from the partial decomposition of legumin. It is al likely that legumin prepared by the ordinary methods is not a homogeneous

Preparation.—Dumas and Cahours employ the following method for the p of legumin, the most advantageous source of which are peas or sweet almo bruised substance is digested for two or three hours with tepid water; the then crushed in a mortar so as to form a pulp; and to this is added abo weight of cold water. After the whole has been macerated for an hour, it on a cloth and pressed, and the liquid portion on standing deposits a certai of starch. The solution is now clarified by filtration, and acetic acid, di 8 or 10 times its weight of water, is gradually added. Immediately on the the acid, a perfectly white flocculent precipitate is formed, which may be easil on a filter and washed with water. Care must be taken to avoid an exces acid, in which legumin is readily soluble. The legumin is then washed wi dried, pulverised, and digested with ether, which removes all fatty mat product is again dried in vacuo at 140° (Gerhardt, *Traité,* iv. 491). Ha cannot well be substituted for the above substance, since they contain matter which renders the filtration and washing exceedingly tedious. to Löwenberg, the product, obtained as above, is a mixture of legumin an and after it has been washed with boiling water, contains a decompositi of legumin, mixed with albumin. The separation of these two substanc effected by dissolving the mixture in ammonia, evaporating off the excess o adding chloride of sodium, boiling, filtering, and precipitating the filtrate acid. The precipitate is washed first with cold water, then with boiling a ether. The infusion of peas and almonds also contains a third body, whic pitated by acetic acid; it is insoluble in excess of the acid, but soluble in The ammoniacal solution is partly precipitated by boiling with chloride of so evaporating the excess of alkali.

Rochleder purifies legumin, prepared by the first method, by treating it centrated potash, which readily dissolves the legumin, and leaves a floccule of another substance. The solution is allowed to stand, decanted, then fi precipitated by acetic acid. The well-washed precipitate is dissolved in filtered again, and reprecipitated by acetic acid.

Properties.—The solution of legumin does not coagulate by ebullition; evaporated, becomes covered with a pellicle, like milk (Liebig). Purified insoluble in cold water; with boiling water it yields a product richer in carb in water and insoluble in acetic acid, together with a less carbonised body, i water (Löwenberg). The body analysed by Dumas and Cahours had th properties:—When precipitated from a concentrated solution by weak ace always presented a nacreous and iridescent appearance; from a weak sol deposited in flakes. It is insoluble in cold alcohol and ether; also in bo and in weak boiling alcohol. It dissolves largely, however, in cold water, the liquid is heated almost to boiling, it coagulates, and gives a precipitate flakes very like coagulated albumin (Gerh. iv. 493). Gerhardt thinks that have experimented with the aqueous extract of legumin obtained directly from which probably contains that substance in combination with alkali, formin agulable solution like the alkaline albuminates. The fresh aqueous extract of the leguminosæ is always neutral; the legumin precipitated therefrom always reddens litmus, even after prolonged washing. When this solution itself, it coagulates in 24 hours, at a temperature of 15 or 20° C., yielding a precipitate like the coagulum of milk. The mother-liquor is decidedly appears to contain lactic acid. (Liebig.)

Digitized by Google

In the following analyses the ash is deducted:—

	Dumas and Cahours.*		Rochleder.†			Rälling.‡	Löwenberg.‖
	Lentils.	*Sweet almonds.*	*Haricots.*			*Peas.*	*Peas.*
Carbon . .	50·46	50·93	54·0	54·3	53·9	50·68	53·9
Hydrogen .	6·65	6·70	7·5	7·4	7·3	6·74	7·2
Nitrogen . .	18·19	18·77	14·7	14·6	15·0	16·50	
Sulphur . .	. .	. .	. .	. .	. .	0·48	0·3
Oxygen . .							

Purified legumin sometimes contains as much as 7·1 per cent. ash (Rochleder). The ash is perfectly white, has an alkaline reaction, and contains a large quantity of potash, partly in combination with phosphoric acid. The insoluble portion of the ash is composed of phosphate of calcium and magnesium, as well as a little phosphate of iron. (Liebig.)

Völcker (Rep. Brit. Assoc. 1857, pr. 60; J. p. Chem. lxxv. 320) found in legumin prepared from peas and beans, the following percentage of ash, phosphorus, and sulphur:

Legumin.	Ash.	Phosphorus.	Sulphur.
From green peas	1·100	1·383	0·870
The same, precipitated with a small quantity of acetic acid . .		1·880	0·571
The same, precipitated with excess of acetic acid		2·180	0·851
From white peas	1·45	1·520	
From white French beans	0·71	1·780	0·590

Norton (Pharm. Centr. 1847, p. 466; 1848, p. 240) also found in legumin prepared from peas, sweet almonds, and oats, from 0·8 to 2·3 per cent. phosphorus. The large amount of phosphorus found by Völcker and Norton renders it probable that legumin contains, or is associated with, a compound of phosphoric acid, perhaps phosphoglyceric acid.

Decompositions.—When legumin is subjected to dry distillation, it swells, yields a yellowish distillate containing carbonate, sulphide, and acetate of ammonium, and leaves a residue of shining charcoal. (Braconnot.)

Legumin distilled with *acid chromate of potassium and dilute sulphuric acid* yields an acid liquid which smells of prussic acid and bitter almond oil, contains a considerable quantity of prussic acid, with a small quantity of formic acid, but does not give the reactions of the aldehydes with potash or with nitrate of silver. When rectified over mercuric oxide, the first portion of the distillate exhibited a more aromatic and ethereal odour than the original liquid; the second portion, which was covered with a thin layer of oil, contained benzoic acid (4 pts. to 1,000 of legumin) valerianic, butyric, propionic, acetic, caproic, and probably also caprylic acid (Fröhde, J. pr. Chem. lxxvii. 290). In a second series of experiments, Fröhde found among the products of oxidation of legumin, valeronitrile, acetonitrile (not distinctly recognised), and a third nitrile, probably propionitrile.

All *acids* coagulate the solution of legumin; the precipitates redissolve in excess of the acid.

When legumin is boiled with *dilute sulphuric acid*, leucine is formed. Dry legumin saturated with *concentrated sulphuric acid* dissolves slowly and forms a brown solution, but no glycocine is produced.

Concentrated *nitric acid* dissolves dry legumin, with evolution of nitrous fumes.

Dilute *hydrochloric acid* precipitates legumin like acetic acid. The concentrated acid dissolves it with the characteristic blue tint.

When gelatinous legumin is placed in contact with concentrated *acetic acid* it absorbs the acid, and swells, becoming semitransparent. The product is completely soluble in boiling water. A gummy residue of legumin, soluble in water, is obtained on evaporation. A solution of legumin is immediately precipitated by dilute acetic acid, and the precipitate is redissolved by an excess of the acid, forming a perfectly clear solution. This is reprecipitated by adding ammonia; the precipitate dissolves in an excess of the acid (Dumas and Cahours). Liebig found legumin insoluble in weak acetic acid; Löwenberg's legumin, which is insoluble in water, dissolves in an excess of acetic acid.

Solution of legumin is precipitated by tribasic *phosphoric acid*, also by *oxalic*, *tartaric*, *malic*, and *citric acids*; the precipitates are readily soluble in excess of acid. Legumin is dissolved in the cold by *potash*, *soda*, and *ammonia*. Heated with fixed alkali, it evolves ammonia, and sulphide of ammonium is formed in the solution.

* The carbon and nitrogen in the other analyses of MM. Dumas and Cahours fall between these two analyses.

† Previously purified by Rochleder's method.

‡ The substance was redissolved in ammonia, precipitated by acetic acid, and exhausted by boiling alcohol and ether.

‖ Purified by Löwenberg's process.

Digitized by Google

Baryta and *lime* form insoluble compounds with legumin, as with casein. Li solution of legumin precipitates many earthy and metallic salts, but does no tate sulphate of magnesium, or the acetate, or other salts of calcium in the applying a slight heat, the liquid rapidly coagulates. Braconnot attributes th ing of vegetables cooked in selenitic waters to the formation of these lime-co

A concentrated solution of legumin, to which rennet has been added, does to coagulate for several hours; after 24 hours all the legumin is precipitat coagulation does not appear from this to be due to the free acid contained in t (Dumas and Cahours). Putrefying legumin acts as a powerful ferment.

Dry beans, peas, lentils, &c., contain, on an average, about 25 per cent. genised matter (legumin, albumin, &c.), and are the most nutritive of vegeta the same time, they are deficient in starch and fat. They are not genera wholesome food in large quantity, except for men enjoying robust health and in severe labour. Legumin appears to be much more indigestible than insolub as casein is far more indigestible than the fibrin of meat. C

LEHMANNITE. Native chromate of lead (i. 934).

LEHRBACHITE. Selenide of mercury and lead from Tilkerode, near L probably a mechanical mixture of the two selenides, inasmuch as specimens ferent parts of the same vein exhibits very different proportions of lead and (see p. 558).

LEHUNTITE. Syn. with NATROLITE.

LEIDENFROST'S PHENOMENON. This term is sometimes appli spheroïdal state of liquids (p. 88), first observed by Leidenfrost.

LEMNA. *Duckweed.*—Plants of this genus are very rich in inorganic su and have accordingly been recommended for use as manure. In a specimen *minor* growing in the river Eure, in France, Hervé Mangon (Instit. 186 found:

Combustible matter (without nitrogen).	Nitrogen.	Silica.	Lime.	Phosphoric acid.	Other mineral constituents.
61·1	3·6	6·7	8·2	1·1	19·3 =

Liebig (Ann. Ch. Pharm. cv. 109) obtained from *Lemna trisulca* growing in 16·6 per cent. ash, and from a litre of the surrounding water 0·415 grm. residue. 100 pts. of the slightly ignited plant-ash, *a*, and of the saline resid water, *b*, contained:

	CaO	MgO	NaCl	KCl	K^2O	Na^2O	Fe^2O^3*	P^2O^5	SO^3
a.	16·82	5·08	5·90	1·45	13·16	. .	7·36	8·73	6·09
b.	35·00	12·26	10·10	. .	3·97	0·47	0·72	2·62	8·27

LEMNIAN EARTH. *Sphragide.*—The Λημνία σφραγίς of the Gr yellowish-grey earth or clay frequently marbled with rusty spots. Dull. fine earthy. Meagre to the touch. Adheres slightly to the tongue. When in water it falls to pieces, with disengagement of air-bubbles. Its con are, 66 silica, 14·5 alumina, 0·25 magnesia, 0·25 lime, 3·5 soda, 6 oxide of water (Klaproth). It has hitherto been found only in the Island of S (ancient Lemnos). It is reckoned a medicine in Turkey; and is dug up onl year, with religious solemnities, cut into spindle-shaped pieces, and stampe seal. In ancient times it was esteemed an antidote to poison and the plague.

LEMON. See CITRUS (i. 1003).

LENTIL. *Ervum Lens.* The air-dried seed of this leguminous plant according to Krocken (Ann. Ch. Pharm. lviii. 224), from 34 to 35 per cent. Horsford (*ibid.* 199) found in 100 pts. of the seed, 30·4 pts. of non-azotised to 2·6 ash and 13·0 water.

Poggiale (J. Pharm. [3]. xxx. 180, 255), and Fresenius found in 10 air-dried lentils, the following constituents:

Starch.	Gum.	Sugar.	Legumin.	Fat.	Cellulose, Pectin, &c.	Ash.	Water.	
44		. .	29·0	1·5	7·7	2·4	15·4	Pogg
35·5	7·0	1·5	25·0	2·5	12·0	2·3	14·0	Fres

Levi found in lentil-seeds from Worms 2·06 per cent. ash of the compositi below.

The straw of lentils contains 0·01 per cent. nitrogen (Boussingault); dried straw contains 27 per cent. water and 34 per cent. substances soluble i alkaline ley, 57 per cent. woody fibre, and 3·9 per cent. ash, having the fo composition:

* With traces of alumina.

Digitized by Google

Composition of Lentil-ash.

	Seed.	Straw.		Seed.	Straw.
Potash	34·6	10·8	Silica	1·3	17·6
Soda	9·5		Phosphoric acid	36·2	12·3
Lime	6·3	52·3	Sulphuric acid		1·0
Oxide of manganese	2·5	3·0	Chloride of sodium	7·6	2·1
Ferric oxide	2·0	0·9			

According to Schwarz, a hectare of ground yields about 1,360 kilogrammes of seed and 3,700 kilogrammes of straw; the former, therefore, containing 30, the latter 144, and the whole, 174 kilogrammes of mineral constituents (Handb. d. Chem. ii. [3] 832).

LENZINITE. A variety of kaolin from the pegmatite of La Vilate near Chanteloupe (Haute Vienne), of a clear brown colour, tender, but not plastic. Before the blowpipe it becomes reddish, but does not fuse. It is decomposed by hot sulphuric acid. Contains, according to Salvétat (Ann. Ch. Phys. [3] xxxi. 102), 36·36 per cent. silica, 36·00 alumina, 1·95 ferric oxide, and 21·50 water (agreeing nearly with the formula $2Al^2O^3.3SiO^2.3H^2O$), besides 0·18 magnesia, 0·50 alkalis, 2·0 gelatinous silica, and 1·64 quartz (=101·62).

LEONHARDITE. A hydrated silicate of calcium and aluminium, occurring at Schemnitz in Hungary, and at Copper Falls, Lake Superior, in monoclinic crystals, in which $\infty P : \infty P = 83° 30'$ and $96° 30'$; $oP : \infty P = 114°$. Cleavage parallel to ∞P, very perfect; basal imperfect. Also columnar and granular. Hardness = 3 to 3·5. Specific gravity = 2·25. Lustre on cleavage-faces pearly; elsewhere vitreous. Colour white, sometimes yellowish, seldom brownish. Subtranslucent. It usually whitens on exposure, like laumontite; but the variety from Lake Superior does not. Before the blowpipe it exfoliates, froths, and easily melts to an enamel. It dissolves in acids.

Leonhardite from Schemnitz has been analysed by Delffs and v. Babo (Pogg. Ann. lix. 336, 339), that from Copper Falls by Barnes (Sill. Am. J. [2] xv. 440):

	Schemnitz.		Copper Falls.
Silica	54·92	55·00	55·50
Alumina	22·49	24·36	21·69
Lime	9·05	10·50	10·56
Water	13·54	12·30	11·93
	100·00	102·16	99·68

The analyses do not agree well together. The first analysis of the Hungarian mineral agrees approximately with the formula $(3CaO.4SiO^2).4(Al^2O^3.3SiO^2) + 15H^2O$, which, however, is improbable; that of the American mineral may be represented by the much simpler formula $(CaO.SiO^2).(Al^2O^3.3SiO^2) + 3H^2O$, or $2CaAl'''Si^2O^8.3H^2O$, which is that of a metasilicate, and differs from the formula of laumontite (p. 472) only in the amount of water. According to Brooke and Miller, leonhardite agrees in form also with laumontite. Delffs found in the mineral 13·55 to 13·81 per cent. water; it gave off 11·64 per cent. at 100°. According to Kenngott, leonhardite is identical with caporcianite. (Dana, ii. 308; Rammelsberg, *Mineralchemie*, p. 806.)

LEOPARDITE. A spotted felspathic rock, occurring at Charlotte, Mecklenburgh County, and in the Steele Mine, Montgomery County, North Carolina, and recognised by Genth (Sill. Am. J. [2] xxxiii. 197), as a true porphyry, spotted with iron- and manganese-compounds. The crypto-crystalline felspathic base is interspersed with small crystals of orthoclase and quartz. Analysis gave:

SiO^2	Al^2O^3	Fe^2O^3	MgO	CaO	Na^2O	K^2O	Loss by ignition.
75·92	14·47	0·88	0·09	0·02	4·98	4·01	0·64 = 100·00

agreeing very nearly with the composition of Bunsen's normal trachytic substance.

LEPAMINE. A volatile base containing the elements of 1 at. diamylamine and 1 at. lepidine; $C^{10}H^{23}N.C^{10}H^9N = C^{20}H^{32}N^2$, produced by the action of iodide of amyl on lepidine (p. 573).

LEPARGYLIC ACID. Syn. with Anchoic acid (i. 289). Arppe has lately shown (Ann. Ch. Pharm. cxxiv. 86) that Laurent's *Azelaic acid* (i. 477) has the same composition as lepargylic or anchoic acid: it appears, however, to differ so much from the latter in melting point, solubility, and the properties of some of its salts, that the two acids can scarcely be regarded as identical (which is Arppe's view), but only as isomeric.

Azelaic acid is most easily obtained by heating castor-oil with 2 pts. of nitric acid,

Digitized by Google

of specific gravity 1·2—1·3, added by small portions, continuing the operati hours, then separating the acid liquid from the remaining oil, adding fresh continuing the oxidation for another day. The acid liquid is then to be separ the oil and added to the former portion, the whole evaporated, with addition and freed from oil, which then separates, by means of a tap-funnel. The solution duly concentrated yields a white granular mass, which, when freed f acid by washing with cold and recrystallisation from warm water, and from c soluble acids by melting the crystals, pulverising the fused mass, and tr powder with water, leaves a mixture of azelaic and suberic acids; and on tr residue with cold ether, the azelaic acid is dissolved, while the suberic aci behind. The ethereal solution is evaporated, the residue is dissolved in hot the solution, freed from any oil that may still remain, is evaporated to the cr point.—Azelaic acid is also obtained in a similar manner, together with sev acids, from almond-oil, spermaceti, and oleic acid (Arppe, Ann. Ch. Ph 288; Jahresber. 1861, p. 357).

Azelaic acid, prepared as above, has the composition $C^9H^{16}O^4$. It cryst cooling from a moderately concentrated aqueous solution, sometimes in larg sometimes in long flattened needles several inches long; the crystals are tr and colourless, with vitreous lustre, but of no determinate form. From a v solution, it separates in smaller laminæ, which under the microscope exhil forms, viz. oblique rhombic prisms with acute angles of about 22°, square t thin flattened prisms. It dissolves in 700 pts. water at 15° (lepargylic acid, according to Buckton, in 217·4 pts. at 18°); it is more soluble in still more in alcohol. It melts at 106° (lepargylic acid at 114—116°, Buck tially at 115°, completely at 124°, Wirz); and volatilises with partial decomp higher temperatures; the vapours excite coughing, but not so strongly a acid. Heated with caustic baryta, it is resolved into carbonic anhydride an of heptyl, C^7H^{16}, together with small quantities of other hydrocarbons; $C^9H^{18}O^4 = 2CO^2 + C^7H^{16}$. (R. S. Dale, Chem. Soc. J. xvii. 261.)

The azelaates of the alkali- and alkaline-earth-metals are soluble in calcium-salt being the least soluble; those of the heavy metals are insolub are all decomposed by dilute *nitric acid*, with separation of crystalline az The neutral salts form with *chloride of calcium* a copious crystalline precip *ferric chloride* a brick-red, and with *cupric sulphate* a blue-green precipitate.

Barium-salts.—The *acid salt*, $C^{18}H^{30}Ba''O^8$, is obtained by neutralising a h of the acid with carbonate of barium. [Buckton did not succeed in preparin anchoate of barium.]—A warm concentrated solution of the acid neutral hydrate of barium yields a granular precipitate of the salt $2C^9H^{14}Ba''O^4.C^1$ which may be crystallised from water, but when washed with hot water is into the *neutral salt*, $C^9H^{14}Ba''O^4$.

The *calcium-salt*, $C^9H^{14}Ca''O^4$, is very sparingly soluble. The *copper-salt*, C^9 is a blue-green precipitate; the *lead-salt*, $C^9H^{14}Pb''O^4$, a white precipit *magnesium-salt*, $C^9H^{14}Mg''O^4.3H^2O$, is efflorescent, and separates from solutio water by evaporation in crystalline crusts. The *manganese-salt*, $C^9H^{14}M$ white fusible precipitate; the *nickel-salt*, an apple-green crystalline precip *silver-salt*, $C^9H^{14}Ag^2O^4$, a white powder.—The *strontium-salt*, $C^9H^{14}Sr''O^4.2$ rates by evaporation from its warm aqueous solution in crystalline crusts, w dried in the exsiccator, give off half their water, leaving granular crystals $C^9H^{14}Sr''O^4.H^2O$. (Arppe.)

LEPIDINE. $C^{10}H^9N$. (Gr. Williams, Edinb. Phil. Trans. xxi. [3] xiv. 103.)—A volatile organic base homologous with chinoline, and obtained with that base, and several others of the series, by distilling quinine or c with water and hydrate of potassium (i. 809). The bases are first sep fractional distillation,—the portion which distils above 199°, especially tha 216° and 243°, consisting of chinoline and lepidine, the latter being found chi portion boiling above 270°,—and the separation is completed by fractiona lisation of their platinum-salts.

A base isomeric, and originally supposed to be identical, with lepidine is in coal-tar oil, and may be separated by collecting and rectifying the port distils between 250° and 267°, and completing the purification by fractional sation of the platinum-salt as above. This base, now called iridoline, is dist from lepidine by its lower boiling point, by certain differences in the ch its salts, some of which crystallise less easily than the corresponding salts of and in particular by the reaction of its amyl-derivative with ammonia (p. 57

Lepidine is an oily base resembling chinoline, of specific gravity 1·07 boiling between 266° and 271° (iridoline boils between 252° and 257°). density, obs. = 5·14, calc. = 4·96.

Digitized by Google

Lepidine is somewhat decomposed by boiling, yielding pyrrhol and carbonate of ammonia. By *iodide of methyl, ethyl* and *amyl*, it is converted into iodide of methyl-, ethyl- and amyl-lepidyl-ammonium (p. 573).

Both lepidine and iridoline form crystallisable salts; the iridoline-salts smell of naphthalene. The *hydrochlorates* of both bases, $C^{10}H^9N.HCl$, form small colourless needles, which do not melt at 100°. They form, with *chloride of cadmium*, crystalline double salts containing $C^{10}H^9N.HCl.CdCl^2$; and with *tetrachloride of platinum*, the salt $2(C^{10}H^9N.HCl).PtCl^4$, which is insoluble in alcohol. The platinum-salt of iridoline crystallises less readily than that of lepidine.

The *nitrates*, $C^{10}H^7N.NO^3$, form hard prisms which are permanent in the air, and do not melt at 100°.

Acid chromate of lepidine, $2C^{10}H^9N.H^2O.2CrO^3$, crystallises in long golden-yellow needles which decompose at 100° when moist, but not when dry, and leave chromic oxide when ignited.—*Acid chromate of iridoline* is an oily compound which does not crystallise.

Derivatives of Lepidine.

Amyl-lepidine. $C^{15}H^{19}N = N\left\{\begin{matrix}C^5H^{11}\\C^{10}H^7\\H\end{matrix}\right.$.—The hydriodate of this base, or iodide of amyl-lepidyl-ammonium, $C^{15}H^{20}NI = N[(C^5H^{11})(C^{10}H^7)H^2]I$, is obtained by heating lepidine with iodide of amyl, in small crystals, slightly soluble in water. This iodide treated with potash or ammonia is converted into a splendid blue compound (Gr. Williams), called iodide of pelamine; the reaction is,

$$\underset{\text{Iodide of amyl-lepidyl-ammonium.}}{2C^{15}H^{20}NI} + KHO = \underset{\text{Iodide of pelamine.}}{C^{30}H^{38}N^2I} + KI + H^2O.$$

When treated with moist oxide of silver, it yields the base, and from this the other salts of pelamine may be obtained (see PELAMINE). The crude distillate from cinchonine treated with iodide of amyl and potash yields a similar blue compound (known commercially as *chinoline blue* or *cyanine* (i. 873), which consists mainly of iodide of pelamine, together with a small quantity of the homologous compound $C^{29}H^{36}N^2I$, derived in a similar manner from chinoline. (Hofmann, Compt. rend. lv. 849; Proc. Roy. Soc. xii. 410).

Diamyline-lepidine or **Lepamine.** $C^{20}H^{27}N^2$ = $C^{10}H^{25}N.C^{10}H^9N$, or perhaps $\left.\begin{matrix}(C^5H^{11})^2\\(C^{10}H^9)''\\H^2\end{matrix}\right\}N^2$. (Gr. Williams, Chem. Soc. J. xvi. 375.)—When lepidine is cohobated with iodide of amyl, a brown syrupy liquid is obtained, which solidifies to a mass of crystals on cooling. On repeatedly boiling this mass with water, the greater part dissolves, yielding a solution of iodide of amyl-lepidyl-ammonium. A considerable portion however remains undissolved, and this portion, if subjected to prolonged ebullition in a retort with caustic alkalis, decomposes, yielding a distillate consisting of water and an oil. The latter dissolves for the most part in hydrochloric acid, and the solution, evaporated to a moderate bulk, forms two layers, the upper, which appears like a colourless oil, solidifying on cooling to a mass resembling paraffin, while the lower is merely a saturated aqueous solution of the same substance. The paraffin-like hydrochlorate, treated with alkalis and distilled, yields diamyline-lepidine as a volatile base, which may be dried with sticks of potash, and rendered nearly colourless by rectification. It has a fragrant odour, and when perfectly dry distils at about 175°. Vapour-density, obs. = 10·40; calc. = 10·38.

Hydrochlorate of lepamine, $C^{20}H^{27}N^2.2HCl$, melts below 100°, is sparingly soluble in water, and must be dried in a vacuum before being heated over the water-bath.

Chloroplatinate.—On adding an excess of strong hydrochloric acid to a solution of the base, so as to obtain the hydrochlorate as an oil floating on the surface, and then a considerable excess of tetrachloride of platinum, an adhesive yellow mass is formed, which may be washed by agitation with cold water, dried over oil of vitriol for a day or two and then over the water-bath. It is perfectly soluble in alcohol, and has the composition, $2(C^{20}H^{27}N^2.2HCl).PtCl^4$.

Gold-salt.—On adding trichloride of gold to a solution of the hydrochlorate, a chocolate-coloured precipitate is formed, which quickly changes to bright green; it is soluble in alcohol, forming a green solution.

Lepamine dissolved in strong *nitric acid* yields a red solution, from which on dilution, a red oil separates, probably a nitro-compound.

By heating lepamine with *iodide of ethyl* in a sealed tube, a syrupy liquid is obtained which when distilled with potash, yields a volatile oily base, probably ethyl-lepamine.

Digitized by Google

It dissolves readily in hydrochloric acid, forming a salt which is much more to crystallise than hydrochlorate of lepamine.

Ethyl-lepidine. $C^{12}H^{13}N = C^{10}H^{8}(C^{2}H^{5})N$.—The hydriodate of this *iodide of ethyl-lepidyl-ammonium*, $[(C^{2}H^{5})(C^{10}H^{7})H^{2}]NI$, is obtained by hea dine with iodide of ethyl, in brown needles, which after recrystallisation, beautiful canary-yellow colour, becoming transiently blood-red at 100°. Tre moist oxide of silver, it yields the corresponding hydrate, which when tre hydrochloric acid and tetrachloride of platinum, yields the platinum-salt, 2C $PtCl^{4}$, soft at first, but soon becoming crystalline.

Methyl-lepidine. $C^{11}H^{11}N = C^{10}H^{8}(CH^{3})N$.—The hydriodate, or iodide o *lepidyl-ammonium*, $C^{11}H^{12}NI$, is obtained in crystals by heating lepidine with methyl.

LEPIDOCROCITE. *Needle Iron ore.*—A hydrated ferric oxide of composition as göthite, $Fe^{2}O^{3}.H^{2}O$ (ii. 940), occurring at Spring Mills, Mo County, Pennsylvania, in minute radiating crystals or granular scales, and aggregations, imbedded in fibrous red oxide of iron, and in nodules of chalce

LEPIDOLITE. Lithia-mica, found at Rogena and Iglau in Moravi island of Utön, Sweden, and in other localities. (See MICA.)

LEPIDOMELANE. A variety of mica, so called from its scaly struc black colour (λεπίς and μέλας), consisting, according to Soltmann's analys Ann. l. 664) of 37·40 silica, 11·60 alumina, 27·66 ferric oxide, 12·43 ferro 9·20 potash, 0·26 lime and magnesia, and 0·60 water, corresponding with the (FeO; $K^{2}O$).($Al^{2}O^{3}$; $Fe^{2}O^{3}$).$2SiO^{2}$, which is reducible to that of an orth $\left.\begin{matrix}M'\\R'''\end{matrix}\right\}SiO^{4}$.

The mineral forms crude masses of granular scaly structure, consisting o scales, sometimes exhibiting the form of six-sided tables; according to Wöhl completely decomposed by hot hydrochloric or nitric acid, the silica separa crystalline scales like those of the mineral. It is found only in one locality in probably at Persberg, Wermland.

LEPOLITE. See ANORTHITE (i. 308).

LEPTYNITE. *Granulite* or *Eurite.* A granular compound of felspar with sometimes containing garnet.

LEUCANILINE. $C^{20}H^{21}N^{3}$. (A. W. Hofmann, Proc. Roy. Soc. xii. 2; ber. 1862, p. 34.)—A base produced by the action of reducing agents on ros and related to it in the same manner as indigo-white to indigo-blue:

$$\underset{\text{Rosaniline.}}{C^{20}H^{19}N^{3}} + H^{2} = \underset{\text{Leucaniline.}}{C^{20}H^{21}N^{3}}.$$

It may be obtained by leaving hydrochlorate of rosaniline in contact with metal or more easily by digesting a salt of rosaniline (or commercial fuchsine or magen sulphide of ammonium. A yellow resinous mass is then formed, which is to l pulverised, washed with water and dissolved in dilute hydrochloric acid. The forms with concentrated hydrochloric acid, a copious, crystalline, brown or precipitate, of impure hydrochlorate of leucaniline, which may be purified by r solution in dilute, and precipitation by concentrated hydrochloric acid. It cry from boiling dilute hydrochloric acid in very small rectangular plates, wh obtained quite pure by recrystallisation from water, or by precipitation of the a solution with ether.

Leucaniline is precipitated from the solution of the hydrochlorate as a white acquiring a faint rose tint on exposure to the air. It is nearly insoluble i sparingly soluble in boiling *water*, whence it separates in small crystals, slightly in *ether*, easily in *alcohol*. It turns red when heated, and melts at 100° to a d transparent liquid, which solidifies to a lighter-coloured mass on cooling. By o agents, such as peroxide of barium, ferric chloride, and especially chromate of pot it is easily converted into rosaniline. It unites with sulphide of carbon, chloride zoyl, and several other bodies, forming compounds which have not yet been exa

The salts of leucaniline crystallise well, especially the sulphate; they are all in water, and are precipitated by acids. The *hydrochlorate*, $C^{20}H^{21}N^{3}.3HCl.H^{2}$ up its water only when heated for a long time in a stream of hydrogen. On its solution with excess of leucaniline, the latter separates out in splendid without forming a less acid salt. The *chloroplatinate*, $2(C^{20}H^{21}N^{3}.3HCl).3PtCl$ is sparingly soluble in cold water, decomposible by boiling water, and gives water with difficulty, even when heated above 100°. The *nitrate*, $C^{20}H^{21}N^{3}.3HN$

Digitized by Google

forms white needles soluble in water and in alcohol, but not in ether, only sparingly in nitric acid, and decomposing at 100°.

Triphenyl-leucaniline. $C^{39}H^{33}(C^6H^5)^3N^3$.—Obtained by the action of reducing agents on triphenyl-rosaniline. The blue solution of the hydrochlorate of this base is decolorised by zinc and hydrochloric acid, and the clear liquid treated with water yields a precipitate which may be purified by solution in ether. The same compound is obtained as a brittle, non-basic resin, by the action of sulphide of ammonium on hydrochlorate of triphenyl-rosaniline. It is anhydrous, and when treated with oxidising agents, is reconverted into triphenyl-rosaniline. (Hofmann, Compt. rend. lvii. 25.)

LEUCAZOLITMIN. See LITMUS.

LEUCHTENBERGITE. A variety of chlorite (i. 914) from Slatoust in the Ural. Breithaupt regards it as an altered chlorite. Komonen found in it only 8·62 per cent. water instead of 12·62, the percentage in normal chlorite. Kenngott regards it as a distinct species.

LEUCIC ACID. $C^6H^{12}O^3$. (Strecker, Ann. Ch. Pharm. lxviii. 55; Gössman, *ibid.* xci. 135; Waage, *ibid.* cxviii. 295; Thudichum, Chem. Soc. Qu. J. p. xiv. 307; Frankland, Proc. Roy. Soc. xii. 396; Frankland and Duppa, *ibid.* xiii. 140.)—An acid, homologous with lactic acid, produced:—1. From *leucine*.—*α*. When nitric oxide gas is passed through a solution of leucine in strong nitric acid, nitrogen is evolved and leucic acid is formed (Strecker). The same reaction takes place when nitrous acid is passed through a solution of leucine in warm water (Thudichum), or water slightly acidulated with nitric acid (Waage):

$$\underset{\text{Leucine.}}{C^6H^{13}NO^2} + \underset{\text{Nitrous acid}}{HNO^2} = \underset{\text{Leucic acid.}}{C^6H^{12}O^3} + N^2 + H^2O.$$

Cahours had previously observed (Compt. rend. xxvii. 368) that a peculiar acid is formed when an aqueous solution of leucine is left to itself.—*β*. When chlorine gas not in excess is cautiously passed through a solution of leucine in caustic soda, leucic acid is formed and may be separated from the mixture in the same manner as benzoglycollic acid (i. 548) from hippuric acid. (Gössmann.)

2. From *oxalate of ethyl*, by the action of zinc-ethyl. The direct product of this action is probably zincoleucic ether, a body not isolated, thus [zn = 32·5 = ½ zn]:

$$\underset{\text{Oxalate of ethyl.}}{C^6H^{10}O^4} + \underset{\text{Zinc-ethyl.}}{\begin{cases} znC^2H^5 \\ znC^2H^5 \end{cases}} = \underset{\text{Zincoleucic ether.}}{C^6H^{10}(znC^2H^5)O^3} + \underset{\text{Ethylate of zinc.}}{zn(C^2H^5)O}.$$

The zincoleucic ether is converted by the action of water into leucic ether:

$$\underset{\text{Zincoleucic ether.}}{C^6H^{10}zn(C^2H^5)O^3} + H^2O = \underset{\text{Leucic ether.}}{C^6H^{11}(C^2H^5)O^3} + znHO;$$

and from this, the barium-salt, and thence the acid itself, is easily obtained. (Frankland.)

Preparation.—1. Pure leucine is dissolved in boiling water slightly acidulated with nitric acid; nitrous acid gas is passed through the warm solution as long as nitrogen continues to escape; the liquid, which turns brown and gradually deposits brown flakes, is left to cool, then agitated several times with ether; and the ethereal extracts are evaporated. The residue is a brown oily liquid not miscible with water, which gradually solidifies to a radio-crystalline mass. The aqueous solution, freed from leucic acid by repeated agitation with ether, left on evaporation a considerable quantity of nitro-leucic acid.—To purify the crude leucic acid thus obtained, it is dissolved in a large quantity of water (a smaller quantity dissolves it but imperfectly); the boiling liquid is mixed with an aqueous solution of acetate of zinc; and the precipitated leucate of zinc is washed on the filter with water (which dissolves but a small quantity of it), purified by recrystallisation from alcohol, then suspended in water, and decomposed by sulphuretted hydrogen. The filtered solution is but very slightly coloured, and when evaporated to a syrup and left to stand, yields leucic acid in colourless needles. If, on the other hand, the zinc-salt be suspended in alcohol and decomposed by sulphuretted hydrogen, the acid is obtained in hard, brittle prisms. (Waage.)

2. Thudichum passes nitrous acid gas through a warm aqueous solution of leucine; evaporates, with addition of leucine, to neutralise the free nitric acid, and prevent it from oxidising the leucic acid; agitates the syrupy residue with ether (or extracts the leucic acid from the aqueous solution by agitation with ether, without previous evaporation; in which case, however, the treatment with ether must be repeated a great number of times)—and purifies the crude leucic acid from adhering brown oil, either by solution in cold water, filtration and recrystallisation,—or by strongly pressing the coloured crystals between bibulous paper—or by precipitating the aqueous solution

Digitized by Google

with acetate of lead, decomposing the washed precipitate with sulphurette and evaporating the filtrate either over the water-bath at a very moder over sulphuric acid.

3. Oxalic ether is mixed with its own weight of zinc-ethyl, in a rounded by cold water, to prevent rise of temperature and the consequent o a secondary reaction, attended with the evolution of large quantities of et hydride of ethyl; towards the end, however, the reaction requires to be ass application of a gentle heat. The mixture, which generally remains fluid, is cooling, with its own volume of water (whereupon torrents of hydride of et from excess of zinc-ethyl, are evolved), and subsequently distilled in a Weak alcohol containing an ethereal oil in solution then passes over, an quantity of the oil may be obtained by adding water to the residue in the continuing the distillation on a sand-bath. The oil is precipitated from t distillate by water, added to that which floats on the surface of the water then dried over chloride of calcium, and rectified. The principal portion, w between 174° and 176°, consists of leucic ether. (Frankland.)

The process may be greatly simplified, and a larger product obtained, by the zinc-ethyl during the reaction, namely by heating a mixture of amalga iodide of ethyl, and oxalic ether to the necessary temperature. The operat considered complete when the mixture has solidified to a resinous-looking this, when treated with water as above, and distilled, yields a considerable leucic ether. (Frankland and Duppa.)

The leucic ether heated with hydrate of barium, is converted into leucate and this when decomposed by dilute sulphuric acid, yields a solution of leu

Properties.—Leucic acid forms colourless needles (Strecker); needl brittle prisms, of the trimetric or monoclinic system, according to the mod ration (Waage); radiary group of needles, having a mother-of-pearl lu beautiful variety of concentric markings, like those of some kinds of (Thudichum); it is heavier than water, and cuts like hard soap, almost acid (Thudichum); it has an acid taste, and reddens litmus (Thudichu taste, and strong acid reaction (Waage). It melts below 100° and solidifie (Thudichum); melts at 73°, and sometimes solidifies at a few degree melting point, sometimes remains liquid even when cooled to 0° (Waa easily soluble in *water* and in *alcohol*, soluble also in *ether*.

Decompositions.—1. Leucic acid volatilises at 100°, apparently without tion. When it is placed on a watch-glass and heated over the water-bath, the glass become fringed with crystals of the sublimed acid, which dissol water, leaving, however, a few flocks, probably consisting of the anhydride. which remains in the middle of the watch-glass is syrupy, dissolves in after prolonged boiling, but is easily soluble in alcohol and ether; it probab sists of leucic anhydride (Waage). The acid heated for some time in the continually gives off acid-smelling vapours, and does not afterwards solidify but remains in the form of an uncrystallisable, dark-brown, smeary syrup dride, which has a very disagreeable odour, remains unchanged, even wh oil of vitriol for weeks, and is nearly insoluble in water, separating from i and sinking to the bottom. A small quantity of this insoluble compound formed, when the aqueous solution, even if dilute, is heated to the boili evaporated (Thudichum). Leucic acid may be boiled with water witho sition, and traces only of it distil off with the water (Frankland).—2. strongly heated in the *air*, gives off thick fumes and blackens, then takes fi with a yellow smoky flame, leaving a small quantity of charcoal, which is easily consumed. (Thudichum.)

Leucates. Leucic acid forms crystallisable salts, the composition which may be represented by the formulæ, $M'C^6H^{11}O^3$ and $M''(C^6H^{11}O^3)^2$ analogous in composition to the lactates, the acid being diatomic and mon acid silver-salt has, however, been obtained, having the composition $C^6H^{11}Ag$ The leucates are for the most part obtained by boiling the aqueous sol acid with the corresponding carbonates (Thudichum). They are less the lactates in water, more soluble in alcohol. (Waage.)

Leucate of Ammonium.—The acid slightly supersaturated with a evaporated, leaves a thick homogeneous residue, in which no trace of crysta be observed, even after drying for several weeks over oil of vitriol. (Th

Leucate of Barium, $Ba''(C^6H^{11}O^2)^2$.—Obtained by digesting the with carbonate of barium, or by heating leucic ether with hydrate of bariu the excess of baryta by carbonic acid, filtering and evaporating (F

Digitized by Google

Waage, Thudichum). It dissolves with moderate facility in warm water and dilute alcohol, and separates from boiling alcohol in beautiful colourless, silky, laminar crystals, which, like most leucates, retain something of the appearance of leucine. (Waage.)

Leucate of Calcium, $Ca''(C^6H^{11}O^3)^2$.—An aqueous solution of the acid neutralised with chalk or milk of lime, and left to evaporate, yields the calcium-salt in fine needles, easily soluble in water and in alcohol.

Leucate of Cobalt, $Co''(C^6H^{11}O^3)^2$.—The dilute aqueous acid boiled with excess of carbonate of cobalt, then filtered and evaporated, deposits light crusts of a pink colour while moist, but of a very pale rose-colour or almost white when dry. The salt is but sparingly soluble in cold water, and not much more soluble at the boiling heat. It crystallises in needles, which, under the microscope, appear to be arranged in globular masses. (Thudichum.)

Leucate of Copper.—When a dilute aqueous solution of leucic acid is treated with a dilute solution of ammonio-sulphate of copper, the colour of the copper-salt changes to light-green. On boiling the liquid, it becomes paler, and on cooling deposits light green granules of leucate of copper. Under high powers of the microscope, these granules appear as balls, formed by a radiary arrangement of needles (Thudichum). A solution of leucic acid mixed with acetate of copper, forms a green flocculent precipitate, very sparingly soluble in water, even at the boiling heat, but easily crystallised from boiling alcohol, from which it separates in very beautiful light blue, shining, bulky scales, which do not undergo any diminution in weight at 100°. (Waage.)

Leucate of Lead.—On adding acetate of lead to a solution of leucic acid or a leucate, a copious white flaky precipitate is formed, which on boiling dissolves almost entirely in the liquid. Any portion remaining undissolved melts into a white mass, which is soft like resin while warm, but becomes brittle and hard on cooling. This substance is insoluble in water and alcohol, even on boiling, and seems to be a basic salt.

If the solution of lead is added to a boiling solution of the acid, no precipitate ensues, acid vapours are evolved, and the liquid becomes milky on cooling. In a short time, it deposits the lead-salt as a light, granular, white mass, which, under the microscope, appears to be made up of a multitude of strongly refracting spherical masses, of the size of human blood-corpuscles. This salt is more easily soluble in an excess of the acetate than in water. It is easily soluble in spirit of wine, particularly in boiling spirit. Even in these solutions, basic salts are easily formed. The addition of water to these solutions produces a precipitate. (Thudichum.)

Leucate of Magnesium.—Sparingly soluble in water, deposited in crusts on evaporation. (Thudichum.)

Leucates of Mercury.—Mercuric Leucate may be prepared:—*a.* Directly, by dissolving freshly-precipitated moist mercuric oxide in aqueous leucic acid. A flaky precipitate gradually ensues, which on heating becomes red and granular, and adheres to the sides of the glass. On cooling, a new precipitate, consisting of whitish globules, is deposited.—*b.* By adding mercuric nitrate to an aqueous solution of leucic acid, a whitish-red precipitate is formed, which dissolves on boiling, and on cooling is again deposited in reddish granules.—*c.* By adding the mercurial solution to the leucate of an alkali-metal.

Mercurous Leucate.—When a solution of mercurous nitrate is added to a solution of leucic acid a slight turbidity ensues. The addition of carbonate of sodium produces a copious reddish-white precipitate, which, on boiling, becomes red, then dull grey, and deposits metallic mercury. (Thudichum.)

The leucates of mercury have a great tendency to become reduced. The mercuric salt easily passes into the mercurous salt. The mercuric salt, moreover, has a great tendency to become basic and insoluble. (Thudichum.)

Leucate of Potassium is produced by the action of aqueous potash on leucic ether, and separates as a semi-solid soap on the surface of the potash-solution, if the latter is concentrated. (Frankland.)

Leucates of Silver.—a. The *neutral-salt*, $C^6H^{11}AgO^3$, is obtained by adding nitrate of silver to the solution of the acid neutralised with ammonia, or by boiling the acid with oxide of silver, and may be rendered quite colourless by recrystallisation from boiling water, in which it is moderately soluble. It is anhydrous (Waage). Nitrate of silver added to a warm solution of leucate of ammonium, potassium, or sodium, forms a copious white crystalline precipitate, which increases as the liquid cools, and blackens if left in the mother-liquor (Thudichum). It contains 45·2 per cent. silver (Waage); 44·14 (Thudichum); calc. 45·19 per cent.

Acid salt, $C^6H^{11}AgO^3.C^6H^{12}O^3$.—A hot dilute solution of leucic acid decomposes recently

Digitized by Google

precipitated carbonate of silver, with effervescence. The excess of the carbonat and the undissolved portion of the leucate become blackish-grey, but the a entirely neutralised. The hot filtrate forms no deposit on cooling. The evaporate it over the water-bath produces a black precipitate of reduced must, therefore, be evaporated in vacuo over oil of vitriol. After prolonged a few crystals, of a glassy lustre and appearing under the microscope as rhombic plates, are deposited at the margin of the dish. The liquid the covered with a pellicle, and evaporation is impeded. At a later stage conglo needles are deposited, which, when carefully dried over sulphuric acid appear a little blackened, like most silver-salts, but are not decomposed. analysis 26·97 per cent.; the formula requires 29·1 per cent. (Thudichum

Leucate of Sodium.—The aqueous acid neutralised with carbonate of so evaporated, leaves a syrupy residue covered with a crystalline crust. When is left over oil of vitriol, crystals form in it, which under the microscope exhi racteristic tub-shape, with rhombic plates interspersed here and there. (Thu

Leucate of Zinc, $Zn''(C^6H^{11}O^3)^2$.—This salt is obtained by neutralising acid at the boiling heat with carbonate of zinc, and filtering at the same te The solution deposits a thin crust on cooling. Evaporated over the wat soon becomes covered with a crust, and on cooling deposits bulky masses o which must be separated by filtration, pressed between bibulous paper, and exposure to the air or over the water-bath. The best crystals are obtain solution containing excess of leucic acid (Thudichum). For Waage's mo paration, see page 575.

The salt is snow-white, with splendid silky lustre; exhibits under the m the appearance of masses of needles (Thudichum); extremely light dazzling whiteness and silky lustre (Waage). It is sparingly soluble even water, less in cold water (Thudichum); dissolves in 300 pts. water at 1 204 pts. boiling water; more soluble in alcohol (Waage). The air-dried sal $Zn''(C^6H^{11}O^3)^2.H^2O$, and gives off its water (5·1 per cent.) at 100° (Waa anhydrous salt gives by analysis, 43·87 per cent. carbon, 6·39 hydrogen, zinc, the formula requiring 44·01 carbon, 6·72 hydrogen, and 19·92 zinc (Thu Sulphydric acid precipitates the zinc completely (Waage); according to T on the contrary, the precipitation is only partial, even after the solution repeatedly saturated with the gas.

LEUCIC ETHER. *Leucate of Ethyl*, $C^8H^6O^3 = C^6H^{11}(C^2H^5)O^3$.—The and preparation of this compound by the action of zinc-ethyl on oxalic e already been described (p. 575). It is a colourless, transparent, somewhat o possessing a peculiar penetrating ethereal odour, and a sharp taste. It is in water, but dissolves readily in alcohol and ether. Specific gravity 0·9613 Boiling point, 175°. Vapour-density, obs. = 5·241; calc. 5·528. Tre hydrate of barium or potassium, it yields the corresponding salts of le (Frankland.)

LEUCINDIN-SULPHURIC ACID. See INDIN-SULPHURIC ACID (p.

LEUCINE. $C^6H^{13}NO^2$. Formerly called *Aposepedine* and *Caseous Oxide.* Ann. Ch. Phys. [2] x. 40; Braconnot, *ibid.* xiii. 119; Mulder, J. pr. C 290; Bopp, Ann. Ch. Pharm. lxix. 20; Laurent and Gerhardt, Ann. [3] xxiv. 321; Cahours, Compt. rend. xxvii. 265; Limpricht, Ann. Ch. Ph 243; Gössmann, *ibid.* xc. 184; xci. 129; Strecker, *ibid.* lxviii. 54; Gm —This substance was first observed by Proust, in 1818, as a product of the pu of cheese; and Braconnot in 1820 found it among the products of decomp animal substances by sulphuric acid; Mulder, in 1838, showed that the two thus obtained were identical.

It is homologous with glycocine ($C^2H^5NO^2$) and alanine ($C^3H^7NO^2$), an regarded as lactamic acid, $(C^6H^{10}O)''\begin{matrix}H^2\\H\end{matrix}\}\begin{matrix}N\\O\end{matrix}$, being related to leucic acid in manner as glycocine to glycollic acid, and alanine to lactic acid.

Occurrence.—In old cheese (Proust). In fresh calf's liver (Liebig, Che 3 Aufl. 453); also, together with tyrosine, in the human liver, in certain disease, but not in the healthy liver (Frerichs and Städeler, Jahresbe 675). According to later researches by these chemists (*ibid.* 1856, 702; 1858, cine and tyrosine are very widely diffused in the animal organism. Leucine a together with taurine, inosite, and uric acid, in the tissue of the lungs (A. Ann. Ch. Pharm. xcii. 289). According to Gorup-Besanez, Ann. Ch xcviii. 7), it occurs in many parts of the glandular system, viz., in the thy thyroïd glands, in the liver, and especially in the pancreas. It has been fou

Digitized by Google

the brain of oxen (W. Müller, Ann. Ch. Pharm. ciii. 131); in the pancreas of oxen (Scherer, Jahresber. 1859, p. 610); in the stomach and intestines of the pupæ of butterflies (Schwarzenbach, *ibid.* 1857, p. 538), and in the fly-agaric, *Agaricus muscarius.* (Ludwig, *ibid.* 1862. p. 516.)

Formation.—1. In the decomposition of gelatin, muscular flesh, legumin or wool (or white of egg, according to Mulder), by sulphuric acid (Braconnot); together with a small quantity of glycocine (Mulder). Gorup-Besanez also (Ann. Ch. Pharm. cxviii. 230), by treating wool with sulphuric acid, obtained, together with volatile acids and a large quantity of ammonia, about 3 per cent. of tyrosine, and a rather large quantity of leucine containing sulphur. The leucine was obtained free from sulphur by dissolving it in rather dilute potash-ley, boiling it with a solution of lead-oxide in potash, filtering from sulphide of lead, neutralising the filtrate with sulphuric acid, evaporating to dryness, boiling the pulverised residue with alcohol, and leaving the solution to crystallise.

2. By heating horn with dilute sulphuric acid (Hinterberger), also together with tyrosine, by heating elastic tissue, especially the cervical ligament (Zollikofer), or feathers, hedge-hogs' spines, human hair, the wing-cases of cockchafers, or globulin and hæmatin from ox-blood (Leyer and Köller, Ann. Ch. Pharm. lxxxiii. 332), or silk (Hinterberger, Wien. Akad. Ber. xi. 450) or conchiolin (Schlossberger, Zeitschr. Ch. Pharm. 1860, p. 424), with dilute sulphuric acid. Erlenmeyer and Schöffer (Zeitschr. Ch. Pharm. 1859, p. 315), by boiling 1 pt. of various albuminous and gelatinous substances with 5 pts. of a mixture of 1 pt. sulphuric acid (H^2SO^4) and 1½ pts. water, obtained the following quantities of leucine and tyrosine: Cervical ligament yielded ¼ per cent. tyrosine and 38 to 45 per cent. leucine; blood-fibrin, 2 per cent. tyrosine (on evaporating the neutral liquid to about 1·08 to 1·10 specific gravity), then 14 per cent. leucine; flesh-fibrin, not quite 1 per cent. tyrosine, and about 18 per cent. leucine; white of hen's egg, 1 per cent. tyrosine and about 10 per cent. leucine; horn (treated with 10 pts. of the above acid mixture), 3·6 per cent. tyrosine, and about 10 per cent. leucine. The several substances were decomposed by three hours' boiling with the acid as completely as when the boiling was continued for 36 or 40 hours.

3. By the action of dilute acids upon indican. (Schunck, p. 247.)

4. By boiling white of egg, gelatin, or flesh, with potash-ley, glycocine being formed at the same time (Mulder). Hence also, when the juice of mangold-wurzel is boiled with lime. (Hochstetter, J. pr. Chem. xxix. 36.)

5. By melting albumin, fibrin, casein (Bopp), or horn (Hinterberger) with hydrate of potassium.

6. In the putrefaction of casein or gluten under water (Proust, Mulder); sometimes abundantly, sometimes only in traces (Cahours). Also, together with tyrosine, ammonia, butyric acid, and lactic acid, by the putrefaction of yeast (A. Müller, J. pr. Chem. lvii. 162, 447). But according to Hesse (J. pr. Chem. lxx. 34), the substance regarded by Müller as leucine contains 3 or 4 per cent. sulphur, and is more soluble in alcohol than leucine (see PSEUDOLEUCINE, p. 582).

7. By the action of hydrocyanic acid and dilute hydrochloric acid, with the aid of heat, on valeral-ammonia (Parkinson, Ann. Ch. Pharm. xc. 144; Limpricht, *ibid.* xciv. 243):

$$NH^3.C^5H^{10}O + CNH + HCl + H^2O = C^6H^{13}NO^2 + NH^4Cl.$$

It was stated by Gössmann, that thialdine is converted into leucine by the action of moist silver-oxide, according to the equation:

$$C^6H^{13}NS' + 2Ag^2O = C^6H^{13}NO^2 + 2Ag^2S;$$

but according to Hofmann (Chem. Soc. J. x. 193), thialdine thus treated gives off the whole of its nitrogen in the form of ammonia.

Preparation.—1. Finely-chopped beef, washed with water and then strongly pressed, is mixed with an equal weight of oil of vitriol, and gently heated till it is completely dissolved; the fat is skimmed off after cooling; the mixture diluted with water amounting to 3½ times the weight of the meat; the liquid boiled for 9 hours, with frequent renewal of the water; the sulphuric acid removed by chalk; the filtrate evaporated to an extract; this extract repeatedly boiled with alcohol of 34° Bm.; the resulting alcoholic tincture evaporated; the dry residue exhausted with cold alcohol; the residual mixture of leucine and a small quantity of matter precipitable by tannin dissolved in water; a solution of tannin carefully added to it by drops as long as any precipitate ensues; and the liquid filtered after a few seconds, then evaporated (Braconnot). The leucine prepared by Braconnot appears still to have contained glycocine. (Mulder.)

2. 1 pt. of dry albumin, fibrin, or casein, free from fat, is boiled with 4 pts. of oil of vitriol and 12 pts. of water, in an open vessel, the ebullition being continued for a day

filtered from calcic oxalate, and evaporated till a crystalline film forms upon its
deposits groups of yellowish laminæ of leucine mixed with tyrosine, more of which
may be obtained by evaporating the mother-liquor. The crystalline mass is t
solved in such a quantity of hot water that the solution on cooling yields cr
tyrosine only; the leucine solution is then decolorised with animal charcoal, eva
and the leucine which separates is purified by pressure and recrystallisation f
alcohol. Waage (Ann. Ch. Pharm. cxviii. 295) proceeds in the same way as Sch
excepting that, after precipitating the last portions of lime with oxalic acid, he m
filtrate with sulphate of copper, precipitates the copper with sulphydric acid; ev
the filtered liquid which is then nearly colourless, to the crystallising point; re
lises the separated leucine from water and dilute alcohol; and finally decoloris
boiling with a small quantity of hydrate of lead, and removing the lead by
dric acid. The leucine thus prepared still retains 2 per cent. ash and a trace of

4. White of egg, gelatin, or flesh, is boiled with potash-ley till it is comple
composed; the liquid neutralised with sulphuric acid, and evaporated; and the
extracted with alcohol. (Mulder.)

5. 1 pt. of the powder of dry albumin, fibrin, or casein free from fat, is added
of hydrate of potassium, heated to fusion in an iron crucible of 25 times the c
and water carefully added after half an hour, when the violent frothing arisi
the escape of water and ammonia has subsided, and the brown colour which t
ture at first exhibits, is changed to yellow; if the liquid be then saturated wit
acid, filtered hot, and gradually cooled, it yields tufts of needles consisting of t
These crystals completely fill the filtrate, when the process is well conducted;
other hand, they are less abundant the longer the fusion has been continue
liquid decanted from the crystals of tyrosine is evaporated till a crystalline film
on the surface; then set aside for 24 hours and exhausted with strong alcoho
leaves crystals of leucine and the still remaining tyrosine; the liquid is mix
alcoholic sulphuric acid, and decanted from the crystallised sulphate of potassi
alcohol separated from it by evaporation, the sulphuric acid by lead, and then
by sulphydric acid; and the solution finally evaporated, whereupon it yields cr
leucine and a greasy syrup, the quantity of which is less in proportion as th
has been longer continued. To purify the leucine from tyrosine and a small
of brown colouring matter, it is dissolved in such a quantity of hot water tha
small quantity of leucine may separate on cooling, together with the tyrosi
mother-liquor is digested with hydrated oxide of lead, which removes the c
matter together with a small quantity of leucine; the filtrate is treated with su
acid; and the filtrate thus obtained, which has merely a yellowish colour, is eva
in a flask till a crystalline film forms on its surface. It then, on cooling, yields

Digitized by Google

f leucine, which must be washed with cold water and alcohol, and decolorised by reatment with animal charcoal and recrystallisation.—If the object be merely to obtain eucine, and not tyrosine, it is sufficient to heat the potash-mixture till the strongest ntumescence is over. At that stage of the process, the same quantity of leucine is ormed, but no tyrosine. (Bopp.)

6. One pt. of cheese, muscular flesh, or white of egg, is left to putrefy with 50 pts. f water for six weeks at a temperature somewhat above 20°; the resulting turbid olution boiled with a small quantity of milk of lime; the lime precipitated by a very light excess of sulphuric acid; the filtrate boiled down and precipitated by neutral cetate of lead; the decanted liquid treated with sulphydric acid; the filtrate evaporated o a syrup; and the leucine which crystallises therefrom, is freed from the remaining yrup by means of alcohol, and purified by solution in water, treatment with hydrated xide of lead and sulphydric acid, crystallisation, and washing with cold water and lcohol. When the above-mentioned alcoholic solution of the syrup is evaporated to omplete dryness, and the residue dissolved in absolute alcohol, the solution still leposits a small quantity of leucine. (Bopp.)

7. The cervical ligament of the ox, after being freed from the surrounding fibrous issue by boiling with water containing acetic acid, and subsequent scraping with a nife, and (if necessary) from fat by digestion in ether, is boiled for 48 or 50 hours with dilute sulphuric acid (8 pts. oil of vitriol to 12 pts. water), the water being replaced as it evaporates. The resulting solution is mixed with a slight excess of thin milk of lime, and boiled for some hours; the filtrate exactly neutralised with sulphuric acid and evaporated; and the liquid, after filtration from the separated sulphate of calcium, is again evaporated: it then yields, especially on cooling, impure leucine, which may be purified by recrystallisation from hot alcohol. This process is peculiarly advantageous, as the acid mother-liquors crystallise to the last drop, yielding nothing but leucine. (Zollikofer, Ann. Ch. Pharm. lxxxii. 162; compare Gössmann, *ibid.* xci. 130.)

8. Valeral-ammonia is boiled in a retort with hydrocyanic and hydrochloric acids till the oily layer consisting of the fused ammonia-compound has completely disappeared; the solution is then left to itself till the greater part of the resulting chloride of ammonium has crystallised out; the hydrochloric acid removed by means of hydrated oxide of lead, and the lead by sulphydric acid; the filtrate is evaporated over the water-bath, and the residue dissolved in hot dilute alcohol: the solution thus obtained yields crystals of pure leucine. (Limpricht.)

Properties.—Leucine crystallises from alcohol in soft nacreous scales, lighter than water and resembling cholesterin. It sublimes completely at 170°, in cotton-like flocks without fusion or decomposition (Mulder); according to Schwanert, on the contrary, it melts at 170°. It is sparingly soluble in cold, but dissolves easily in hot *water*; sparingly in alcohol of ordinary strength (in 658 pts. of cold alcohol of specific gravity 0·828 according to Mulder), very sparingly in absolute alcohol. According to Zollikofer, it dissolves in about 27 pts. of cold water, in 1040 pts. of cold alcohol of 96 per cent., and in 800 pts. hot alcohol of 98 per cent. It is insoluble in ether. Its solubility in water and alcohol is increased by the presence of acetic acid, or an alkaline acetate.

Decompositions.—1. Leucine heated to 180°, yields a yellow distillate having an ammoniacal odour, and solidifying in the cold, while a brown resinous mass remains in the retort. The alcoholic solution of the distillate has an alkaline reaction, and when treated with hydrochloric acid, gives off carbonic anhydride, and yields a solution containing hydrochlorate of amylamine, together with sal-ammoniac. The resolution of the leucine into carbonic anhydride and amylamine, which is the principal reaction, is similar to that of phenyl-carbamic acid into carbonic anhydride and phenylamine, and shows that leucine may be regarded as amyl-carbamic acid:

$$\underset{\text{Leucine.}}{C^6H^{13}NO^2} = CO^2 + \underset{\text{Amylamine.}}{C^5H^{13}N}. \quad \text{(Schwanert.)}$$

—2. Leucine heated in contact with the air burns readily, and with a white flame. —3. An alkaline solution of leucine exposed to the action of *ozone*, yields carbonic acid, butyric acid, and other volatile fatty acids, ammonia, and probably also, in the earlier stage of the decomposition, cyanic acid and valeraldehyde (Gorup-Besanez, Ann. Ch. Pharm. cxxv. 210).—4. Leucine is decomposed by *chlorine*, forming a hard brown body, similar to that obtained with glycocine (ii. 903), and a red volatile liquid (Mulder). When chlorine is passed into water in which leucine is suspended, carbonic anhydride is evolved, and a turbid solution is formed, from which an oily liquid separates, consisting of a mixture of valeronitrile and chloro-valeronitrile (C^5H^8ClN): the solution contains hydrochlorate of leucine (Schwanert). —5. *Sulphuric anhydride* is rapidly absorbed by leucine, forming a brown viscid liquid, which at 100° gives off

Digitized by Google

carbonic and sulphurous anhydrides, and if then distilled with water, y grant liquid boiling at 97°, and forming crystalline compounds with the a of the alkali-metals; probably, therefore, valeraldehyde (Schwanert).- heated for some time with a sufficient quantity of *nitric acid*, is comple into gases, but so long as the decomposition is incomplete, the still remai exhibits the characters of nitrate of leucine (Mulder).—7. When nit passed into a solution of leucine in nitric acid, nitrogen is evolved, and le $C^6H^{12}O^3$, is formed (Strecker, p. 575). The same acid is formed whe passed, not in excess, into a dilute solution of leucine in caustic soda (G —8. Chlorine gas passed to saturation into a solution of leucine in carbon sium, forms chloride of cyanogen, valerianic acid, and valeronitrile (G —9. Leucine distilled with *peroxide of manganese* and dilute *sulphuric* valeronitrile and carbonic anhydride:

$$C^6NH^{13}O^2 + O^2 = C^5H^9N + CO^2 + 2H^2O.$$

When stronger sulphuric acid is used, valerianic acid passes over, and the tains ammonia. When leucine is distilled with *peroxide of lead* and v trace of valeronitrile passes over, but a large quantity of butyral and th which crystallise together in the form of butyral-ammonia.—10. By *perm* it is resolved into ammonia, oxalic acid, and valerianic acid (Neubau Pharm. cvi. 59).—11. Leucine fused with *hydrate of potassium*, gives off a hydrogen and forms valerate of potassium (Liebig, Ann. Ch. Pharm 12. An aqueous solution of leucine emits a very offensive odour, and form acid, perhaps leucic acid (Cahours).—In a vacuum, the aqueous solutio appears to remain undecomposed (Gössmann).—13. When a solution leucine in water is set aside for some weeks in contact with a quantity of which in the dry state would weigh ½ pt., putrefaction takes place, part of the leucine is decomposed, and ammonia is produced, together v quantity of valerianic acid as cannot be wholly produced from the fibrin.

Combinations.—1. With acids. Leucine dissolves easily in acids, formin able salts. The *hydrochlorate*, $C^6H^{13}NO^2.HCl$, forms crystals very soluble in *nitrate*, $C^6H^{13}NO^2.HNO^3$, called also *nitroleucic acid*, forms colourless needl *of leucine and barium* contains 41·01 per cent. baryta (Mulder). *Nitra and calcium* forms mammellated groups containing water of crystallisation. *leucine and magnesium* forms small granular crystals. Leucine also forms salt with *nitrate of silver*. These salts have probably the formula $C^6H^{12}N$

2. With bases. Leucine dissolves readily in caustic *alkalis*, but without them. The aqueous solution of leucine does not precipitate the solution of salt excepting basic acetate of lead.

Cupric salts.—Recently precipitated cupric oxide dissolves readily in aqu forming a bluish liquid, which, on cooling, deposits crystalline grains having the colour of ammoniacal sulphate of copper, and containing CuO

or $C^{12}H^{24}C''uN^2O^4.H^2O$. (Gössmann.)

Lead-salts.—On cautiously adding ammonia to a boiling aqueous solutio and neutral acetate of lead, nacreous scales are deposited containing PbO.2 $C^{12}H^{24}Pb''N^2O^4.H^2O$ (Strecker, Ann. Ch. Pharm. lxxii. 89). Gössmann salt of the same composition; but in one experiment, perhaps in conse peculiar degree of concentration, he obtained laminated groups of crystals lepidolite, and containing $9PbO.2C^6H^{13}NO^2$.

Mercuric salt.—Recently precipitated mercuric oxide dissolves very rea considerable quantity in aqueous leucine; and the solution, when evaporat first crystalline granules and afterwards laminæ containing 47·3 per ce oxide: therefore $HgO.2C^6NH^{13}O^2$ or $C^{12}H^{24}Hg''N^2O^4.H^2O$. (Gössmann Aqueous leucine is not precipitated by mercuric nitrate or chloride; but of potash or ammonia, a white bulky precipitate is formed, which dissolv of potash: the precipitate gradually becomes gelatinous and decomposes du (Gössmann). According to R. Hoffmann, on the contrary (Ann. Ch. Ph 123), pure leucine is precipitated by mercuric nitrate in white flakes, colouring of the supernatant liquid, the production of such a colour in presence of tyrosine.

Aqueous leucine added to a solution of *mercurous nitrate* throws dow dance of white flocks, the supernatant liquid acquiring a red colour. (Br

Pseudoleucine. This name is applied by Hesse (J. pr. Chem. lx sulphuretted compound nearly related to leucine, found by A. Müller products of the decomposition of yeast (p. 579). It contains 3 or 4 per c and is perhaps $C^{36}H^{78}N^6O^{12}S$. It is more soluble in alcohol than leucin

Digitized by Google

purified as completely as possible, forms a white spongy mass composed of shining laminæ. When cautiously heated, it sublimes almost without decomposition. It melts at 210°, and when distilled in an atmosphere of carbonic anhydride, yields, together with more volatile compounds containing nitrogen and sulphur, a woolly mass of acicular crystals resembling phlorizin, having the composition $C^6H^{11}NO$, and dissolving in dilute soda-ley with evolution of ammonia; this substance is designated by Hesse, **leuconitrile**. The other products of the dry distillation of pseudoleucine are sulphydric acid, hydrocyanic acid, a brownish, tarry, fetid substance, and several volatile bases, including ammonia, methylamine, dimethylamine, tritylamine, and a considerable quantity of amylamine.

LEUCITE. A silicate of aluminium and potassium, $(K\overline{\overline{Al}})Si^2O^6$, occurring in monometric crystals, the usual form being the ikosi-tetrahedron or trapezohedron, hence called leucitohedron (*fig.* 180, ii. 125). Cleavage cubic, very imperfect; surface of crystals even, but seldom shining. The mineral often occurs disseminated in grains, rarely in granular masses. Hardness = 5·5 to 6. Specific gravity = 2·483 to 2·49. Lustre vitreous. Colour ash-grey or smoke-grey, white. Streak uncoloured. Translucent to opaque. Fracture conchoïdal. Brittle. Infusible before the blowpipe, except with borax or carbonate of calcium, with which it melts with difficulty to a clear globule. Gives a fine blue with cobalt-solution.

Analyses.—*a.* From Albano near Rome (Klaproth, *Beitr.* ii. 39).—*b.* From Pompeii (Klaproth, *ibid.*).—*c.* From Somma (Awdejew, Pogg. Ann. lv. 107).—*d.* From Vesuvius, eruption of 1811 (Rammelsberg, *ibid.* xcviii. 143).—*e.* From Vesuvius, eruption of 1845 (Rammelsberg, *ibid.*).—*f.* From Rieden on Lake Laach (Bischof, *Chem. Geologie*, ii. 2288):

	a.	*b.*	*c.*	*d.*	*e.*	*f.*
Silica . .	54	54·5	56·05	56·25	57·84	56·22
Alumina . .	23	23·5	23·03	23·26	22·85	23·07
Potash . .	22	19·5	20·40	20·04	12·45	13·26
Soda . .	. .	. .	1·02	0·43	6·04	6·40
Lime . .	. .	. .	. .	0·32	0·20	0·23
Ferric oxide .	. .	. .	. .	. .	0·14	0·48
Loss by ignition	. .	. .	. .	. .	0·59	
	99	97·5	100·50	100·30	100·11	99·66

The formula $(K\overline{\overline{Al}})Si^2O^6$ or $K^2O.Al^2O^3.4SiO^2$ requires 55·58 silica, 23·16 alumina, and 21·26 potash. The potash is sometimes replaced to a considerable extent by soda, as in *e.* and *f.* Abich found in a specimen from Vesuvius a still greater amount of soda.

Leucite occurs in volcanic formations, both ancient and modern; it is abundant in trachyte between Lake Laach and Andernach on the Rhine; the finest and largest crystals are, however, obtained from Vesuvius. Near Rome, at Borghetta on the north, and Albano and Frascate to the south, some of the older lavas appear to be almost entirely composed of it. This leucitic lava is used to form millstones, and millstones made of it have been discovered in the excavations at Pompeii.

Leucite occurs altered to felspar, nephelin, and kaolin. Leucite altered to glassy felspar has been observed on Somma by Scacchi. (Dana, ii. 231; Rammelsberg, *Mineralchemie*, p. 645.)

LEUCOCYCLITE. Syn. with APOPHYLLITE.

LEUCOHARMINE. Syn. with HARMINE.

LEUCOLINE. An organic base obtained from coal-tar, isomeric with chinoline, C^9H^7N. The two bases having this composition, the one obtained by the dry distillation of quinine and cinchonine, the other among those of the distillation of coal, were formerly thought to be identical, and the name chinoline was applied to both. Subsequent researches, however, having pointed out important differences between the two, especially in their behaviour with iodide of amyl, the base obtained from cinchonine is now distinguished as chinoline, and the coal-tar base (originally called *leucol* by Runge, who discovered it) as leucoline (see i. 869).

Each of these bases has a series of homologues corresponding with it, and differing in a similar manner from their isomers in the other series. The following names have been proposed by Greville Williams (Chem. Soc. J. xvi. 377) to distinguish the isomeric bases of the two series:

Coal series.		*Cinchonine series.*
Leucoline . .	C^9H^7N . .	Chinoline
Iridoline . . .	$C^{10}H^9N$ . .	Lepidine
Cryptidine . .	$C^{11}H^{11}N$ . .	Dispoline

The higher homologues of chinoline, as far as $C^{16}H^{21}N$, have also been obtained; the corresponding bases in the leucoline series are at present unknown. (Proc. Roy. Soc. xiii. 312.)

LEUCOLITE. Syn. with PYCNITE.

LEUCONE. $Si^4H^6O^5$.—A white substance obtained by the deco silicone, $Si^4H^4O^3$, under the influence of light and water (Wöhler, Ann. cxxvii. 268). See SILICIUM.

LEUCONIC ACID. *Oxycroconic acid*, $C^5H^6O^6$. (Will, Ann. Ch. P 117; Lerch, *ibid.* cxxiv. 20.)—An acid produced from croconic acid oxidation and assumption of water:

$$C^5H^2O^5 + O + 3H^2O = C^5H^8O^9.$$

When a solution of croconate of potassium is treated with chlorine or nit decolorised and converted into leuconate of potassium, in the latter cas tion of nitric oxide.

The acid [? prepared by decomposing the barium-salt with sulphuric a colourless syrup, which when heated above 100° turns yellow, and is co croconic acid. It is tribasic, and forms white or pale yellow salts, which being easily converted into croconates, especially in presence of alkalis.

The *barium-salt*, $C^{10}H^{10}Ba^3O^{18}$, is obtained as a flocculent, yellowish-wh tate by adding baryta-water to the solution of the potassium-salt, prepar till it becomes alkaline. (Will.)

The *lead-salt*, $C^{10}H^{10}Pb^3O^{18}$, and the *silver-salt*, $C^5H^2Ag^3O^9$, are light-yel tates.

Potassium-salt. When a solution of croconate of potassium decoloris with chlorine or nitric acid, is neutralised with caustic potash or carbonate o the liquid, just at the point of saturation, exhibits a transient play of c colourless to purple-red, bluish-red and yellowish; and if the solution is c an abundant yellowish-white precipitate is formed at the same time, whic in a large quantity of water. This precipitate was found by analysis to h position $C^5H^7KO^9$, but the lead-salt obtained from it by precipitation wit lead exhibited the normal composition $C^{10}H^{10}Pb^3O^{18}$, whence it is probal sparingly soluble potassium-salt with 1 at. metal really consisted of the tri mixed with free leuconic acid (Will). According to Lerch, the solution o potassium-salt is decomposed by neutralisation with potash, yielding a sm of a black salt, probably dihydrocarboxylate of potassium (p. 190), to oxalate and a colourless crystallised potassium-salt.

LEUCONITRILE. A product of the decomposition of pseudoleucin

LEUCOPHANE. A silicate of glucinum and calcium, occurring together with albite, elæolite and yttrotantalite, on a small rocky islet nea of the Langesundfiord in Norway, where it was found by Esmark. It is tr imperfect cleavage in three directions inclined to one another at angles of 53 but usually occurs massive and columnar. Hardness = 3·5 to 4. Specif 2·974. It is more or less translucent, with pale dirty green or light wine-y and yields a white powder, strongly phosphorescent when heated or stru wise becomes electric when heated. It is optically biaxial. Before the melts to a clear bead with a tinge of violet, becoming turbid by flaming easily in borax to an amethyst-coloured glass; in phosphorus-salt it leaves silica; and with a small quantity of carbonate of sodium, it melts to a which, with a larger quantity of carbonate of sodium, sinks into the cha fused phosphorus-salt in an open tube, it gives the reaction of fluorine. an analysis by Rammelsberg (*Mineralchemie*, p. 764), it contains:

SiO^2	F	GO	Al^2O^3	CaO	MgO	Na^2O	K^2O
47·03	6·57	10·70	1·03	23·37	0·17	11·26	0·30

with traces of ferric and manganous oxides, a composition which may be by the formula, $4NaF.3(2CaO.2GO.3SiO^2)$.

Melinophane, from the zircon-syenite of Norway, is nearly related in co leucophane.

LEUCOPHYLL. A colourless substance isomeric with chlorophyll, Sacc (Jahresber. 1859, p. 561) to be contained in those parts of plant capable of turning green, and to undergo this change under the influenc rendered active by the agency of light. The existence of such a substance probable, according to Sacc, by the fact that the plasma of those vegetable quickly turn green on exposure to light, contains a substance which instan a bright verdigris-green colour when brought in contact with strong su and that the same reaction is exhibited by the ready-formed light green chlorophyll itself, whereas the plasma of cells which do not turn green i not exhibit it.

LICHENIC ACID. See FUMARIC ACID (ii. 741).

LICHENIN. $C^6H^{10}O^5$. (Gm. xv. 119.)—A substance isomeric with starc in several species of moss and lichen, especially in the so-called Iceland mo *islandica*), which is really a lichen. According to Maschke (J. pr. Chem formed from starch by the action of the free acid in the plant. It is ext Iceland moss by macerating the chopped lichen for twenty-four hours with a tity of cold water containing a small quantity of carbonate of sodium, and the treatment till the liquid no longer tastes bitter. It is then boiled with the boiling decoction is strained through a linen cloth. The liquid on coolin to a kind of jelly, which dries up to a hard brittle mass (Berzelius). Pay the bitter matter by washing the lichen successively with ether, alcohol gravity 0·83 and 0·90, cold water, very weak solution of carbonate of sodi hydrochloric acid of the strength of 1 per cent., and pure water. Dav N. Phil. J. xxviii. 260) macerates 112 lbs. of Iceland moss for a for potash-ley prepared from 4 lbs. of pearlash, or for six days with milk of li from 6 lbs. of lime, then washes with dilute hydrochloric acid, and water. Chloride of lime may also be used for the maceration. Knop and S mann (Ann. Ch. Pharm. lv. 164) treat Iceland moss with a large quantit chloric acid, and precipitate the solution, after dilution and straining, w The precipitated lichenin is then freed from water and rendered friable treatment with absolute alcohol, and freed from adhering hydrochloric mersion in running water.

Lichenin in the dry state forms a hard brittle mass, tasteless, but hav odour resembling that of lichens. In cold water it swells up without dissolves in boiling water, and is deposited in the form of a jelly; by prolon however, it loses the property of gelatinising, and is converted into a stance, probably dextrin. When the solution in boiling water is left to ev lichenin separates as a rough pellicle on the surface. Lichenin is insolubl and ether.

Dilute acids dissolve lichenin and convert it into glucose. *Nitric acid* it converts it into oxalic acid. Pure lichenin is merely coloured yellow by a green or blue colour is often produced, from admixture of starch.

LICHENS. The following enumeration of the proximate constituent is given by Rochleder in *Gmelin's Handbuch*, viii. 94:

Bæomyces roseus, Pers. See analysis by Brandes. (Berl. Jahrb. xxv.

Biatora lucida, Fr. Contains usnic acid. (Knop, Götting. gelehrte 1843, 2 u. 3 Stück, 16; and Ann. Ch. Pharm. xlix. 103.)

Cetraria aculeata, Fr. Contains no cetrarin, but moss-starch (lichenin) a (fumaric) acid. (Weppen, Pharm. Centr. 1838, No. 12.)

Cetraria islandica, Ach. Contains: fumaric acid (Schödler, Ann. xvii. 87) and cellular substance; starch not deposited in granules, but un tributed among the cells (lichenin); cetraric acid, lichenstearic acid, tall sugar, gum, yellow extractive matter, a brown substance formed from ce and a body not exactly determined (Knop and Schnedermann, lv. lichen always contains alumina (Knop, J. pr. Chem. xxxviii. 347). It cont quantity of a carbohydrate (lichenin) convertible into sugar. (C. Schmid Pharm. li. 29).

Cladonia digitata, Hoffm.
Cladonia macilenta, Hoffm. } contain starch. (Knop, *loc. cit.*)
Cladonia uncinata, Hoffm.

Cladonia pyxidata, Spr. Contains a large quantity of a carbohydrate into sugar. (C. Schmidt, *loc. cit.*)

Cladonia rangiferina, Hoffm. (*Lichen rangiferina*, L.) Contains (Rochleder and Heldt, Ann. Ch. Pharm. xlviii. 13), and a large quanti hydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Evernia furfuracea, Mann. (*Parmelia*, Ach.) Contains usnic acid (H and **Helot**, *loc. cit.*). See an analysis of this lichen grown on a pine-tre (Chem. Schr. vi. 41.)

Evernia ochroleuca, Fr. (*Parmelia sarmentosa*, Ach.) Contains usnic aci *loc. cit.*)

Evernia prunastri, Ach. Contains usnic and evernic acids (Stenhouse [3] xxxii. 300). Rochleder and Heldt found lecanoric, but not a tra acid.

Evernia vulpina. The experiments of Bebert (Ann. Ch. Pharm. ii. 3 so-called vulpulin, seem to show that this lichen contains chrysophanic aci lius, Jahresber. xii. 256.)

Gyrophora pustulata, Ach. (*Umbelliaria*, Hoffm.) From Norway. Contains gyrophoric acid. (Stenhouse, Phil. Trans. 1849, p. 458.)

Isidium corallinum, Ach. Contains a large quantity of oxalate of calcium. (Braconnot, Ann. Ch. Phys. [2] xxviii. 319.)

Lecanora Parella, Ach. (*Parmelia*, Schaer.) Contains: three fats, tannin, parellic acid, lecanoric acid, chlorophyll, and gum, which gives a greenish-blue colour with iodine (Schunck, Ann. Ch. Pharm. liv. 257). The several species of *Lecanora* contain lecanoric acid. (Schunck, *ibid.* xli. 157.)

Lecidia candida, Ach. (*Psora*, Dec.) Contains a large quantity of oxalate of calcium. (Braconnot, *loc. cit.*)

Lecidia geographica, Schaer. From the Brocken. Contains usnic acid. (Knop, *loc. cit.*)

Parmelia ciliaris, Ach. (*Borrera ciliaris.*) See analysis by John. (Chem. Schr. vi. 39.)

Parmelia parietina, Ach. Contains chrysophanic acid, a yellow non-crystallisable colouring matter (Rochleder and Heldt, *loc. cit.*), and a carbohydrate convertible into sugar (C. Schmidt, *loc. cit.*) This lichen contains: a yellow and a red colouring matter, wax, crystalline stearin, chlorophyll, soft resin, gum, lichenin, vegetable mucilage, sugar, extractive matter, traces of volatile oil, and phosphate of calcium (Hesberger, Buchn. Repert. xlvii. 179); compare Sander (*Ueber die Wandflechte*, Sondershausen, 1815; and Kastn. Arch. viii. 431); Monnhardt (*Dissert. sist. Lobariæ parietinæ Analysin chem.* Kielonise, 1818); Schröder (Berl. Jahrb. 1819, p. 44); Markowitz (Scher. Ann. i. 438); Thomson (Ann. Ch. Pharm. liii. 252 and 260).

Parmelia physodes, Ach. Contains crystallised physodin. (Gerding, *Arch Pharm.* lxxxvii. 1.)

Parmelia saxatilis, Ach. Contains a small quantity of carbohydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Patellaria hæmatoma, Hoffm. (*Parmelia*, Ach.—*Patellaria rubra*, Hoffm.—*Parmelia*, Ach.—*Patellaria ventosa*, Dec.—*Parmelia*, Ach.) Contain large quantities of oxalate of calcium (Braconnot, *loc. cit.*). *P. hæmatoma* and *P. ventosa* contain usnic acid. (Knop, *loc. cit.*)

Patellaria tartarea, Dec. (*Parmelia*, Ach.) Contains large quantities of oxalate of calcium (Braconnot, *loc. cit.*) In a specimen from Norway, Stenhouse (*loc. cit.*) found gyrophoric acid. See analysis by N. v. Eserbeck (Ber. Arch. xvi. 135).

Peltigera canina, Hoffm. Contains a carbohydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Pertusaria communis, Dec. Contains a large quantity of oxalate of calcium.

Placodium ochroleucum, Dec. (*Parmelia saxicola*, Ach.) and *Placodium radiosum*, Dec. (*Parmelia radiosa*, Ach.) Contain very large quantities of oxalate of calcium. (Braconnot, *loc. cit.*)

Ramalina calicaris, Fr. var. *fastigiata*. Contains large quantities of starch, colouring matter and bitter substance, and a small quantity of saccharic acid (Berzelius, Scher. Ann. iii. 97). Contains usnic acid. (Rochleder and Heldt, *loc. cit.*)

Ramalina calicaris, Fr. var. *fraxinea*. The ash contains a large quantity of ferric oxide, but scarcely a trace of potash (John, Chem. Schr. vi. 37); soluble and coagulable albumin (Berzelius, Scher. Ann. iii. 208); lichenin, and usnic acid (Rochleder and Helot, *loc. cit.*)

Roccella Montagnei, Belen. Contains erythric acid. (Stenhouse, *loc. cit.*)

Roccella tinctoria, Ach. This lichen (var. *fuciformis*, from Angola and Madagascar) contains erythric acid (Heeren's erythrin, Kane's erythrilin, ii. 502), a fatty substance, roccellic acid, a brown substance extractable by potash, chlorophyll, and ash-constituents (Schunck, Phil. Mag. J. [3] xxix. 194). *Roccella tinctoria* from South America was found by Stenhouse (Phil. Mag. [3] xxxii. 300) to contain α-orsellic acid; the same lichen from the Cape of Good Hope contained β-orsellic acid and roccellinin. Stenhouse and Scouler are of opinion that the *Roccella tinctoria*, var. *fuciformis* analysed by Schunck, was really *R. Montagnei*.

Squamaria elegans, Fée. Contains chrysophanic acid. (Thomson, Ann. Ch. Pharm. liii. 266.)

Squamaria lentigera, Dec. (*Parmelia*, Ach.) Contains a very large quantity of oxalate of calcium. (Braconnot, *loc. cit.*)

Sticta pulmonacea, Ach. Contains lichenin and a bitter principle (Weppen, Pharm. Centr. 1838, No. 12) very near cetraric acid in composition, and named stictic acid by Knop and Schnedermann (J. pr. Chem. xxxix. 303); compare John (Chem. Schr. vi. 39).

Ulcolaria esculenta, Ach. Contains a large quantity (13 per cent.) of gum. (Kirchhoff, Scher. Ann. iii. 213.)

Ulcolaria scruposa contains a large quantity of oxalate of calcium (Braconnot, *loc. cit.*)

Digitized by Google

Usnea barbata, Fr. Contains usnic acid (Rochleder and Heldt, lichenin. (Berzelius, Scher. Ann. iii. 205.)

Usnea barbata, Fr. var. *florida*. (*Usnea florida*, Hoffm.) Contai (Knop, *loc. cit.*), and a small quantity of carbohydrate convertibl (C. Schmidt, *loc. cit.*)

Usnea hirta, Hoffm. (*U. barbata* var. *plicata*, Fr.) Contains usnic *loc. cit.*), bitter principle, gum-sugar, lichenin and a soft skeleton (Berz Ann. iii. 203). Contains a large quantity of carbohydrate convertibl (C. Schmidt, *loc. cit.*)

Variolaria amara, Ach. Contains picrolichenin (Alms, Pharm. Zeit 17; Ann. Ch. Pharm. l. 61.) Contains chlorophyll, and a colourless, bitter substance, forming with ammonia a red non-bitter resin (Gregor Juin 1835, p. 314; Pharm. Centr. 1835, No. 39). Contains picrolicheni chlorophyll, gum-sugar, bitter extractive matter, oxalate of calcium, sili and cellulose (A. Müller, Pharm. Centr. 1844, No 47); compare Filh chardt. (J. de Méd. de Toulouse, vii. 201, and Pharm. Centr. 1844, N

Variolaria communis, Ach. (grown on a lime-tree). Contains waxy colouring matter, a bitter and acrid principle, uncrystallisable sugar, oxal (4·7 per cent.), a substance resembling animal gelatin, &c. (Brac Chim. Phys. [2] vi. 132.)

Variolaria dealbata, Dec. (*Lichen dealbatus*, Ach.) See analysis by Rol Ch. Phys. [2] lxii. 236), who found variolarin in this lichen, and prepared

LICHENSTEARIC ACID. $C^{14}H^{24}O^{3}$. (Schnedermann, and Kn Pharm. lv. 149.)—An acid existing in Iceland moss (*Cetraria islandica*), also in the fly-agaric or toadstool (*Agaricus muscarius*) (Bolley, Ann. lxxxvi. 50). To prepare it, Iceland moss is boiled for a quarter of an h containing carbonate of potassium; the strained decoction is mixed with ex chloric acid; and the whole is diluted with 4 or 5 volumes of water. Th thereby formed is washed with water, and afterwards boiled three or fo alcohol of 42 to 45 per cent. On cooling the alcoholic solution, a mixt stearic and cetraric acids with a third substance, is separated, from whic stearic acid is taken up by boiling rock-oil, and again deposited on coo completely on partial distillation. Purification is effected by recryst alcohol, with the help of animal charcoal.

Properties.—The acid forms a loose, white mass, consisting of delica laminæ having a pearly lustre. From a solution in very dilute alcohol i in small rhombic tables; on concentrating the solution, partly in oily dro odorous, has a rancid, harsh, not bitter taste, melts at about 120° wi weight, and solidifies to a crystalline mass; is not volatile.

It is perfectly insoluble in *water*, but dissolves readily in *alcohol*, *ether*, fixed and volatile.

The *salts* of lichenstearic acid are permanent in the air, and are de acids, with separation of lichenstearic acid. Their solutions froth up on

Ammonium-salt.—The easily prepared solution of the acid in warm aq nia forms, on cooling, a white, elastic jelly, appearing under the microsco a quantity of long, extremely delicate crystals. The salt, when dry, is wh and only partially soluble in warm water, with loss of ammonia.

The *barium-salt*, $C^{28}H^{46}Ba''O^{6}$, is obtained, on precipitating the aqueous l of sodium with a soluble barium-salt, as a greyish white precipitate, wh gether in boiling water.

The *lead-salt*, $C^{28}H^{46}Pb''O^{6}$, is obtained, by precipitating the aqueous sod neutral acetate of lead, in white flakes, which, on boiling the liquid, melt semi-fluid mass. It is brittle, softens between the fingers, and becomes 100°, at which temperature also it appears to decompose.

Potassium-salt.—A solution of the acid in aqueous carbonate of potas down, when concentrated by evaporation, yellowish flakes, which are solu but insoluble in alkaline liquids. If the solution be evaporated to dry residue extracted with boiling absolute alcohol, a part of the salt is cooling, as an indistinctly crystalline powder; and the remainder, on conc solution, in the form of a syrup. It dissolves easily in water, forming liquid, which tastes like soap, and froths up on boiling.

The *silver-salt* is thrown down from a solution of the sodium-salt, by nitr as a greyish-white precipitate, turning violet on exposure to light, and cak in boiling water. It decomposes below 100°.

most of the phenomena known in Newton's time, is altogether unable to acc vast number of facts which have since been discovered. The wave-theory i now universally accepted as the true representative of the phenomena.

The existence of a fluid or medium, such as the theory supposes to ex celestial spaces, may be regarded almost as a matter of certainty: for the comets are found to be retarded in a manner which cannot be accounted other hypothesis. This phenomenon has been particularly studied in the case comet, which revolves about the sun in a period of three years. Now th found to be continually diminishing, showing that the comet is gradually a the sun, an effect which can only be accounted for by supposing its mo retarded by the action of a resisting medium. Moreover, as the light- transmitted freely, not only through the celestial spaces, but also through glass, and other transparent media, we must likewise suppose that the spac the molecules of these bodies are filled up by the ether. It will hereafte that the elasticity of the ether is different in different media.

In the present article, after speaking of the sources of light, we shall en show how the wave-theory is applied to explain the several phenomena of R Interference, Reflection, Refraction, Absorption, and Polari

The chemical action of light will be treated in a separate article.

Sources of Light.

The sun, the fixed stars, certain meteors, and terrestrial bodies in th incandescence and phosphorescence, shine by their own light; all other restrial or celestial, are visible only when the light of a self-luminous body them. Our knowledge of the peculiar conditions which render bodies se is not very exact; but assuming that vision is produced by undulations pervading elastic medium, we must suppose that these undulations are vibratory movements in the particles of luminous bodies. This suppositio over in accordance with the conclusions deduced from the phenomena of he The particles of all bodies are supposed to be in a state of constant mot depends upon the intensity and rapidity of this motion whether the effect p our senses by the undulations thereby excited in the surrounding ethereal that of heat alone, or of heat accompanied by light. We shall see he the non-luminous heat-waves are of less rapid vibration than those which li duce light. Accordingly when the temperature of a body is gradually rai gives out heat unaccompanied by light; but at a certain temperature, the become rapid enough to excite in the ethereal medium, waves which prod organs the sensation of red light, and at still higher temperatures vib produced of a rapidity corresponding to those which excite the sensation of of blue light, which, together with the red, produce the combined sensatio light. (See Radiation of Heat.)

A body may be raised to the temperature necessary to render it luminou chemical action (combustion) going on within its own mass (*e. g.* the burnin wood, hydrocarbons, &c.), or by heat imparted to it from without, as by the of a neighbouring body, by the electric current, by mechanical agen friction or percussion, or by the sun's rays concentrated upon it by a lens Matter in either of the three states of solid, liquid, and gas, may be brough candescent or self-luminous state; flame, indeed, is merely incandescent g explained in the article Combustion (i. 1094), solids become luminous at a temperature than gases, and give out much more light at any given te hence the brightest flames are those which contain suspended particles of s raised to a very high temperature by the heat of the combustion.

The light of the sun and of the fixed stars is in all probability due to inca indeed recent observations have shown that the luminous atmosphere contains many of the metals which exist in our own globe, and similar o have been made on several fixed stars.

Phosphorescence.—Many bodies, under peculiar circumstances, are t such a state of vibration that they emit light without perceptible evoluti Phosphorus, in the state of slow combustion which takes place on exposing at ordinary temperatures, gives off acid vapours, which shine in the dark w bluish light: hence the term *phosphorescent* has been extended to all bodie hibit a similar luminosity, from whatever cause it may arise. The phos of decayed bodies of plants and animals, as of dead wood and putrid familiar to every one. The flowers of certain living plants, especially those yellow or red colour, as *Calendula officinalis, Tropæolum majus, Helianthus*

Digitized by Google

Papaver orientale, have been observed to emit a sudden flashing light on fine summer evenings, a little after sunset. Some plants also emit in the dark a faint continuous light, probably arising from the combustion of some substance, such as a hydrocarbon, emitted from them; this phenomenon has been observed in the leaves of *Phytolacca decandra*, which shine at night, sometimes with bluish-green, sometimes with yellowish-green light. The acrid milky juice of *Cipo de Cananum* (a Brazilian plant, probably of the euphorbiaceous order) emits light for several hours, after flowing from a wound in the plant. *Rhizomorpha subterranea*, a plant which grows in mines, emits light from its whole surface, but especially from the whitish growing points, and a similar phenomenon has been observed in other subterranean plants.

A more familiar kind of phosphorescence is that exhibited by many living animals, as by the glow-worm and fire-fly, and the numberless small marine animals, such as crustacea, medusæ, polypora, and infusoria, which give rise to the phosphorescence of the sea at night. In many animals the phosphorescence is an act of the will; in others it takes place at a particular period of life.

In nearly all phosphorescent plants and animals, the phosphorescence appears to be due to chemical action, in fact to a slow combustion: for it increases in brightness in pure oxygen gas, and ceases altogether in a vacuum or in nitrogen or carbonic acid gas; the phosphorescence of decaying fish, however, takes place in nitrogen as well as in air or oxygen.

Phosphorescence may be excited artificially in a large number of bodies by any cause which sets their particles in rapid vibration; viz., by *heat*, by the *electric discharge*, by *mechanical action*, and by *insolation*.

1. Many solid bodies become phosphorescent when thrown upon a heated surface; such is the case with diamond, chalk, certain varieties of fluor-spar, oyster-shells, paper, flour, especially that of maize, and indeed with most well-dried organic substances. This effect is not to be confounded with incandescence, for it takes place at temperatures much below an ordinary red heat; and the light emitted is generally of a blue or violet tint, instead of the dull red of incipient incandescence.

2. A lump of sugar through which a powerful electric discharge is passed, shines for several seconds afterwards with a beautiful violet light; and a similar effect is produced on many non-conducting minerals, but not on metals or other substances of good conducting power. Substances which have lost the faculty of becoming phosphorescent by heat or by insolation, recover it after they have been subjected to repeated electric discharges. There can be but little doubt that the immediate effect of the discharge is to throw the particles of the body into a state of rapid vibration, which is then communicated to the surrounding ethereal medium.

3. The phosphorescence produced by friction, percussion, and other mechanical actions, generally lasts only as long as the disturbing cause continues to act. In many cases a development of electricity takes place at the same time, and to this the light may be partly or in some cases wholly due; sometimes, however, the light emitted appears to be a direct consequence of the vibratory motion communicated to the particles by the mechanical disturbance. Adularia struck with a hammer so as to split it, emits at each crack a light which may last for several minutes; and when ground in a mortar, it appears all on fire. Quartz, fluor-spar, rock-salt, and sugar likewise exhibit light when broken or pounded.

Light is often emitted during the change of state of bodies, especially in the passage from the amorphous to the crystalline state, and the separation of crystals from a solution (i. 200).

4. *Insolation*, or exposure to the sun's rays, develops phosphorescence most easily in substances which are bad conductors of heat. Most calcareous substances are capable of becoming phosphorescent by insolation: *e. g.* carbonate and sulphate of calcium, fluor-spar, petrifactions, shells, and pearls.

Canton's phosphorus, prepared by heating calcined oyster-shells with sulphur, emits after insolation a yellow light bright enough to show the time by a watch. The phosphorescence may even be excited by exposure to the light of a candle. The *Bolognian phosphorus*, prepared by strongly igniting heavy spar with gum-tragacanth, emits, after insolation, a bright light which lasts for more than a day. *Baudoin's phosphorus* (fused nitrate of calcium) emits a white light. Diamonds sometimes remain phosphorescent for an hour, after exposure to the sun for a few seconds only. Certain organic substances, *e. g.* flour, sugar, gum, white wax, and resin, also shine after insolation.

From recent researches by E. Becquerel, it appears that the number of bodies rendered phosphorescent by insolation, is much larger than has hitherto been supposed, phosphorescence, lasting for a few seconds, or rarely for a few minutes, being exhibited by numerous minerals and salts, chiefly with alkaline or earthy bases. (See *Daguin's Traité de Physique*, iv. 250.)

Digitized by Google

For numerous details relating to phosphorescence, see *Gmelin*
(i. 181—209).

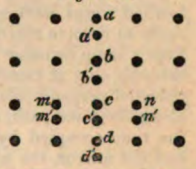
The Electric Light.—The passage of electricity, when it meets with a
ance, is accompanied by light, more or less bright in proportion to the st
charge and the degree of resistance. As the discharge in all cases, eve
highly rarefied atmospheres, such as Gassiot's tubes (ii. 391), takes place
medium of material particles, we may suppose in this case also that the
origin to vibrations excited in these particles by the electric action.

Radiation.

To understand the manner in which the vibrations of luminous bodi
mitted in waves or undulations through the surrounding ether, it will be
consider shortly the nature of undulations in general. A *wave* or *u*
a disturbance excited in one part of a body, and communicated to the o
regular succession. For example, a stone thrown into water depresses
the part where it is thrown in; the portion so depressed exerts a latera
those immediately surrounding it; and these again exert an upward pre
particles external to them, and form a raised circle; afterwards these port
in falling, push up other particles, situated external to them, and thus th
continually spreads outwards in concentric circles till it extends to the who
the liquid. Now it is important to notice that these particles have no
motion; they merely move up and down, as may be seen by observing t
a light body floating on them: there is an appearance of progressive moti
only an appearance, arising from the same form or state of motion being
communicated to the different parts of the liquid. The wave travels onwa
for miles, or, as in the case of the ocean tide-wave, all round the glo
individual particles of water merely move in vertical lines through spaces
ing a few feet. Again, in the case of the waves in air which produce
individual particles of air merely move backwards and forwards through sm
the motion being first excited in the particles immediately in contact with t
body, afterwards communicated by these to the next, and so on, and this
tion of the vibratory motion from particle to particle constitutes a wa
Here again the progress of the wave must be carefully distinguished from
of the individual particles. Sound travels through the air at the rate of
feet in a second; now if the individual particles of air whose vibration p
sound were to rush onwards at that rate, every sound would be accompani
turbance of the air amounting to a hurricane.

Thus it is also in the case of light. The motions of the individual part
ether take place through immeasurably small spaces, but are commun
immense rapidity to the next; from these to those beyond them, and
through the vast distances between the heavenly bodies. So long as the et
which the light-wave travels is of uniform density—as we must suppose it t
space, and in media of uniform constitution, such as water, glass, and ot
tallised bodies—the wave spreads with equal velocity in all directions; co
all the particles to which the motion extends at the same instant are situ
surface of a sphere having the luminous body in its centre, and the illuminat
in lines at right angles to this wave-surface, that is to say, in straight lin
from the luminous body: these lines are called rays of light. When an
density takes place in the medium, the wave-surface is no longer perfectly sp
the rays are broken or curved according as the change of density is sudden

The vibrations of the particles of an elastic medium may be of two kinds
or *longitudinal*, when the line of vibration coincides with, or is parallel to, t
in which the wave travels onwards, as in the case of sound-waves in air.—2.
or *normal*, when the particles vibrate in directions at right angles to the m
wave, as is the case with waves in water, and with the vibrations of a stre
set in motion by drawing a bow across it.



Suppose a particle of an elastic medium to be disturbed in any direction
This direction will in general be oblique to the line joining this particle wi
and the actual velocity of the particle may be resolved into three others,
direction of the line of junction between the two particles, that is to
direction in which the wave-motion proceeds, the other two in a plane at r
to it. The first component determines the longitudinal, the other two
motion or vibration of the particle; and the relative distances to which thes
of vibration are propagated depends upon the peculiar constitution of th

The light which passes between the teeth of t reflected perpendicularly from a plane mirror placed at a great distance; it t along the same path, and again passes between the teeth of the wheel. N the time occupied by the light in travelling twice over the space betwee and the mirror, the wheel will have performed a certain part of its revolut it turns with a due degree of velocity, the light which has passed in the fi between two of the teeth will strike, at its return, on the face of a tooth i space between two teeth, so that an observer looking through the wheel in t of the mirror, will not, in that case, perceive any light. The time whic takes to pass from the wheel to the mirror and return, is therefore equal which a tooth of the wheel moves into the place previously occupied b immediately preceding it, which time is easily calculated from the known the wheel and the number of its teeth. If, for example, the wheel has s makes t revolutions per second, each tooth will pass into the place of th tooth in $\frac{1}{n\,t}$ of a second, and into the place of the space next preceding, second. Fizeau's experiments, in which the wheel and mirror were placed a of 8633 metres (between Turesnes and Montmartre), gave, as the velocity air, 78,841 leagues of 4 kilometres each per second. Römer's method g leagues.

Fizeau's method might be applied to show that rays of light of all colours of sound of every pitch) travel with the same velocity. This conclusion ma be regarded as established by the fact that all the stars, whatever may be t exhibit equal aberration, which could not be the case if rays of different colo with different velocities.

β. *By means of a Revolving Mirror.*—This method, proposed by Arago, out independently by Foucault, and by Fizeau and Breguet, is similar in that by which Wheatstone determined the velocity of electricity, and afford

Fig. 642.

of measuring the velocity of light in a space not exceeding four metres. A li S (*fig.* 642), proceeding from a very narrow rectangular aperture at right an plane of the figure, after passing through the converging achromatic lens K, w form an image of it at S′, falls upon a plane mirror, *mn*, capable of revolving o axis passing through *o* on the line S S′, which reflects it to *s*′, a point symmetri as regards the mirror. At this point is placed a concave spherical mirror

Digitized by Google

centre of figure is in o. The light falling on this mirror is reflected back again along the same path, $s'o$, to the plane mirror, mn, which again reflects it to S in a beam coinciding with the incident light. This will be the case in all positions of the mirror mn, provided the light is reflected from it to M. As the image thus sent back to S would be confounded with the incident beam, an unsilvered plate of glass, ab, is placed in such a position, that the light falling upon it in the direction oS may be partly reflected to s, where it may be observed by an eye-piece furnished with a vertical wire. If the mirror mn be made to revolve slowly, an eye placed at s will see the image of the line of light at intervals, but if the mirror makes more than 10 turns in a second, the image will be seen continuously; and if the eye-piece be adjusted, so that the image shall coincide with the wire, when the mirror makes from 20 to 30 revolutions per second, it will be seen to deviate in the direction of the rotation when the rate is increased to several hundred turns per second; if, for example, the mirror turns in the direction of the arrow, the image will be displaced from S to R, or from s to r. The cause of the displacement is that the mirror mn has time to revolve through a sensible angle, during the time occupied by the light in travelling from o to s' and from s' to o, so that the beam of light, at its second reflection from mn, is deflected from its first direction, forming, with the incident beam So, an angle equal to twice the angular displacement of the mirror.

The mode of calculating the velocity of light from the observed deviation is as follows:—Let $Sc = r$; $co = l$; $os' = l'$; the arc of deviation SR or $sr = d$; also let n be the number of turns performed by the mirror mn in a second, and V the velocity of the light. The mirror mn having moved into the position $m'n'$, by the time that the ray reflected from M returns to it, the deviation would be equal to the angle SoR, if the ray were not deflected by the lens cK, or, which comes to the same thing, if the point c coincided with o. Suppose, first, that this is the case; then the angle SoR is equal to twice the angle α, through which the mirror revolves during the time occupied by the light in passing over the space $2os' = 2l'$. This time is $\frac{2l'}{V}$, and since the mirror makes n turns in a second, the angle $\alpha = \frac{2nl'}{V}$. The angle of deflection of the ray is therefore $\frac{4nl'}{V}$, and the corresponding arc, whose radius is $oS = r + l$, is

$$d = 2\alpha . 2\pi . \frac{\overline{oS}}{} = \frac{8\pi nl'(r+l)}{V}.$$

But the reflected ray is actually deflected by the lens K. Draw R'c through the optic centre c and the point R', which is the image of s' in the mirror $m'n'$. The image of R', formed by the lens K, will then be at E, and the angle of deviation will be $ScE = \delta$. Now the triangles $oR'S'$, $cR'S'$, give $\sin R'cS' = \sin \delta = \frac{R'S'}{S'c} = \frac{R'S'}{l+l'}$; and $\sin R'oS' = \sin 2\alpha = \frac{R'S'}{l'}$. Hence, replacing the angles (which are very small) by their sines, and substituting for 2α its value $\frac{4nl'}{V}$, we find $\delta = \frac{4nl'^2}{V(l+l')}$; and for the arc $SE = D = 2\pi r\delta$:

$$D = \frac{8\pi l'^2 nr}{V(l+l')}; \text{ whence } V = \frac{8\pi l'^2 nr}{D(l+l')},$$

a formula which gives the velocity of light as a function of the deviation.

The same method serves also to measure the velocity of light in water or any other liquid, a tube T containing the liquid, and closed at the ends with flat glass plates, being interposed between the mirror mn and M'. As, however, the light would be refracted by the liquid, and therefore the focus would not fall on M', a diverging lens is placed at L to compensate for the deviation thence arising.

Moreover, as the column of water does not occupy the entire space between the mirrors, the velocity calculated as above from the observed deviation is only the mean velocity of light in a space occupied partly by water and partly by air. Let U be this mean velocity; w and a the spaces occupied by the water and air respectively; V' and V the corresponding real velocities. The times occupied by the light in traversing the spaces a and w are $\frac{a}{V}$ and $\frac{w}{V'}$, and the whole time is $\frac{aV' + wV}{VV'}$. Hence, dividing the total space $a + w$ by the time, we find for the mean velocity:

$$U = \frac{VV'(a+w)}{aV' + wV},$$

whence

$$V' = \frac{wUV}{(a+w)V - aU}$$

By this method it is found that the velocity of light in water is less than in air, a

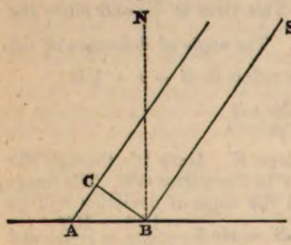
result which, as will be seen hereafter, is in accordance with the wave-t
it is directly opposed to that which would follow from the theory of emiss



Intensity of Light. The intensity of the light received by a surfa
given source—that is to say, the quantity of light received by a unit of t
depends partly on its distance from that source, partly on the obliquity
light falls upon it.

1. *The intensity of light emanating from a point varies inversely as t
the distance.* For, as the undulations excited by the luminous source
equal velocity in all directions—supposing the medium uniform—they
garded as spreading out in concentric spherical surfaces of continuall
magnitude; and as these surfaces are to one another as the squares of t
follows that the quantity of light received by a unit of surface will vary
the square of the radius of the sphere of which it forms a part—that is t
square of its distance from the luminous point.

If the luminous body is of finite dimensions, the preceding law, being
the light emanating from each point of its surface, must likewise hol
regard to the whole, provided the body is sufficiently distant to admit of
being regarded as equally distant from the illumined surface; and since
diameter varies inversely as the distance, *the intensity of the light will v
proportion to the square of the apparent diameter* or to the *apparent su*
luminous body, understanding by this last term the conical angle of a c
ing the body and having its vertex at the luminous point.

2. *The intensity of the light received by any surface varies as the cosine
which the incident rays make with the normal to that surface.* For
(*fig.* 643) to be a portion of the illuminated surface, so small that the
upon it may be regarded as parallel.

their areas; but B C = A B. cos A B C = A
the angle which the incident rays ma
normal B N.

3. *The intensity of the light emanating
luminous surface, is proportional to the
angle which the rays make with the no*
proportion may be demonstrated in a sir
to the preceding, and the result may
by looking through a small aperture at an incandescent surface, as tha
iron, and inclining it more and more to the direction of the rays proceedi
the eye. In accordance with this law, it is found that the brightness of
surface is independent of its form and of its position with regard to the
the impression produced by it on the eye being the same as that produce
surface of equal intrinsic lustre, which is the projection of the original
plane perpendicular to the visual rays: a red-hot ball, for example, seen fro
looks just like a flat disc.

Comparison of the Intensity of two Luminous Sources: PHOTOMET

The eye is not capable of judging directly, with any great approach to
the relative intensity of two lights, but it can perceive with great nicety
contiguous surfaces or portions of the same surface are equally illuminated
two contiguous shadows have or have not the same depth. On this princi
structed most of the instruments called *Photometers*, for measuring the re
sity of different sources of light.

Rumford's *Photometer*, which is very easily constructed, consists
wooden cylinder set upright in front of a sheet of white paper, also place
The two lights to be compared (a candle and gas-flame, for example) are p
same height in front of the paper, and in such a manner that the two sha
wooden cylinder which they cast, shall fall on the paper close together, a
rays from both of them shall meet the paper at the same angle. Each
then be illuminated by only one of the lights, while the rest of the surface
the rays from both, and the two shadows will be of the same depth when
of the paper is equally illuminated by both lights. If then the strong
moved farther off till the shadows are equally dark, the intensities of the
directly as the squares of their distances from the screen when that cond
filled.

Digitized by Google

This photometer gives very exact results in many cases; but in applying it to determine the relative illuminating power of a gas-flame and a candle, a difficulty arises from the different colours of the two shadows, that of the gas being bluish-brown, while that of the candle is yellowish-brown. In all such cases, Bunsen's photometer, whose indications do not depend on depth of shadow, is much more convenient.

Bunsen's *Photometer* consists of a screen of thin writing paper stretched on a frame, and saturated with a solution of spermaceti in oil of turpentine, except a spot in the centre about the size of a shilling. A light of constant intensity being placed at a fixed distance behind the screen, the ungreased spot appears darker than the rest of the screen. One of the lights to be compared is then placed in front of the screen, so that its reflected rays may be added to the light transmitted from behind, and adjusted so that the ungreased spot shall be illuminated just as much as the rest of the surface, and shall therefore be no longer visible. This will be the case when $T + r = t + R$, denoting by T, t, the quantities of light transmitted by the uncovered part of the screen, and the part covered by the disc respectively, and by R, r, the quantities reflected. A precisely similar experiment being then made with the other source of light, the intensities of the two will be to one another as the squares of their distance from the screen at which the disappearance of the disc takes place. Sometimes the grease is applied only to a small circular spot in the centre of the screen, which then transmits more light than the rest of the surface.

Masson's *Electro-photometer*. This apparatus has the advantage of admitting of the comparison of lights of different colours. It consists of a circular disc divided into white and black sectors of equal size, and set in motion by clock-work at a uniform rate of 250 to 300 revolutions in a second. If it be then illuminated by a constant source of light, such as a lamp, it appears of a uniform grey tint, in consequence of the duration of the visual impression on the eye. But if it be illuminated by an instantaneous light, such as the electric spark, the black and white sectors become distinctly visible, and appear as if they were fixed, because they have not time to move through a sensible angle during the extremely short interval for which the spark continues. If now the intensity of the light afforded by the spark be gradually diminished, as by removing it to a greater distance, the source of constant light still remaining, the increase of illumination which the spark affords to the disc ultimately becomes too feeble to render the sectors visible, so that the disc still continues to exhibit a uniform grey tint. The relative intensities of the constant and instantaneous lights at which this limit is attained, evidently depend upon the number of the sectors and the velocity of revolution.

The relative intensities of two electric sparks are as the squares of the distances to which they must be removed from the disc to cause the sectors to disappear, while the disc is illuminated by a constant light. On the other hand, to use the instrument for comparing the intensities of two continuous lights, a succession of electric sparks is made to pass in front of the disc, and one of the constant lights is made to approach it till the sectors cease to be distinguishable. The same experiment being then made with the other light, the intensities of the two are as the squares of the distances thus determined.

By means of this instrument, M. Masson has demonstrated the following laws relating to the intensity of the electric light. 1. *It is proportional to the coated surfaces by the discharge of which, at a constant distance, the spark is produced.* 2. *It is inversely as the distance between those surfaces, or as the thickness of the jar.* 3. *It is proportional to the square of the striking distance.* 4. *The quantities of light in the spark are proportional to the quantities of heat developed in a wire forming part of the same circuit.*

General results of photometric observation.—1. By comparing the quantities of light emitted by the same number of flames in different relative positions, it is found that flame is perfectly transparent; in fact the luminous effect of a series of candles placed side by side, is the same whether they are arranged in a line perpendicular or parallel to the direction of the rays. In like manner, a flat gas-flame, like that of a bat's-wing burner, gives the same amount of light in all directions.

2. It appears from observations by Bouguer, made with Rumford's photometer, that one of the shadows thrown by lights of equal brightness disappears when one of these lights is placed 8 times as far from the screen as the other—that is to say, when the nearer light illuminates the screen 64 times as strongly as the other. Hence it appears that light emanating from any source becomes imperceptible in presence of another 64 times as strong; the disappearance of the stars in daylight shows, therefore, that the diffused light of the earth's atmosphere must be at least 64 times as strong as that sent to us from any of the stars.

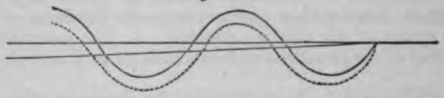
3. When the flames of two lamps or candles touch one another, the intensity of the

Digitized by Google

combined flame is greater than the sum of the intensities of the separate fla effect, first observed by Franklin, appears to be due to the increased tem the part where the flames overlap. Rumford found that a number of flat c impregnated with oil, gave a much greater amount of light when they w together nearly in contact, than when they were separated. On the sam Arago and Fresnel have constructed lamps for light-houses, in which a concentric wicks are arranged with small spaces between them, through w rent of air is made to pass by the draught of a chimney. The flame being t a considerable amount of light is thus obtained within a small space.

4. The photometric method serves also to determine the illuminating eq different light-giving materials. Rumford found that 100 pounds of wax b form of a taper, were equal in light-giving power to 101 lbs. of tallow, if were well snuffed, and 229 lbs. if the wicks were allowed to grow long; of olive oil burnt in an Argand lamp, and 129 in a lamp burning with also to 125 lbs. of rape oil, and 120 lbs. of linseed oil in a common lam calculated the following table of the expense per hour of various modes of il yielding a quantity of light equal to that afforded by a gas-jet burning at 5 centimes per hour:

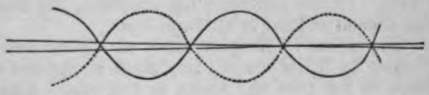
	Centimes.		
Carcel lamp	5·8	Wax taper of 100 grm. . .	
Candle of 82 grm. . . .	9·8	Stearine candle . . .	
Candle of 10 grm. . . .	12·0		



It appears from this comparison that gas is the most economical of all i materials. The results depend, however, in a great measure on the facili of air to the flame, the form of the wick or burner, and the length of the numerous determinations of the illuminating equivalents of various kinds other light-giving substances, see *Ure's Dict. of Arts, &c.*, articles Coal- and Illumination (ii. 493).

Interference.

When two or more waves pass over the same part of a medium, each of t the particles of the medium disturbed by the other just as it would have affect particles in a state of rest. Consequently, the state of any particle affected waves at once, will be the same as that which would have resulted if it ha disturbed by the one wave, and then the second had acted upon it while i turbed state. Thus the height of the tide is found by calculating the heigh it would be raised by the sun and by the moon acting separately, and taki or difference as the case may be.



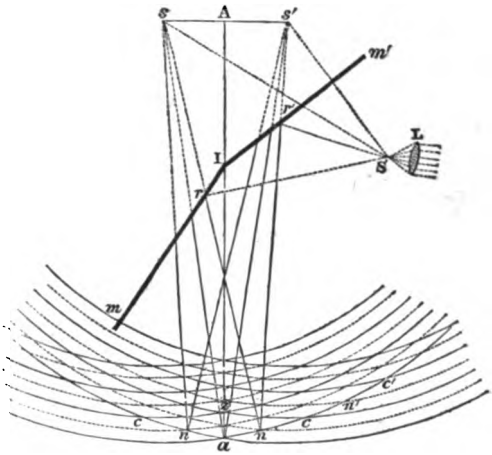
Suppose now two waves of equal breadth and intensity (equal height in water) to proceed from the same, or nearly the same point, and travel o after the other; then, if they meet in such a manner that the phases or alt the one coincide with the phases or alternations of the other, the result wil pound wave, having the sum of the intensities of the separate waves; this case if the paths along which they travel before meeting are of equal lengt exceeds the other by any exact number of whole undulations, as in *fig.* 644 phases of the one are exactly opposed to the phases of the other, which

Fig. 644.

when the one wave is behind the other by any odd number of half-undula *fig.* 645, a wave will be produced whose intensity equals the difference of the

Fig. 645.

of the separate waves, and if these are equal, the vibratory motion will be destroyed and the particles of the medium brought to rest along the whole combined waves. If the paths of the two waves do not differ by any exact half undulations, even or odd, the result will be intermediate between th considered, the intensity of the combined wave being always less than th



Digitized by Google

greater than the difference of the separate waves. This composition or superposition of oscillations is called Interference. In order that it may take place along a whole line of wave, it is clear that the component waves must be of the same breadth, and that they must proceed from points very near each other, otherwise their paths will intersect only at isolated points.

Let us now enquire whether these principles are applicable in the case of light. If light consists of undulations, and these undulations are governed by ordinary mechanical laws, it must follow that two rays of light may meet one another in such a manner as to counteract each other's action and produce darkness; and such, in fact, is found to be the case.

Suppose s, s' (*fig.* 646) to be two radiant points very close together, and producing in the luminiferous ether, waves of the same length (of red light, for example) and always in the same phase of vibration at the instant of starting from these points. Imagine also two series of spherical wave-surfaces having the points s, s' for centres, and with radii increasing successively by half the length of a wave $= \frac{\lambda}{2}$. These surfaces will cut the plane of the figure in two systems of arcs, which will intersect one another in the manner shown in the figure, in which each two consecutive arcs, one represented by a full, the other by a dotted line, are separated by the interval $\frac{\lambda}{2}$, and each pair of alternate arcs (both full or both dotted) by the interval λ, or a whole undulation.

Fig. 646.

Consider now the point a, situated on the line Aa, drawn perpendicular to ss', through its middle point A. The two rays sa, $s'a$, being of equal length, are in the same phase of vibration: consequently their intensities will be added to one another and will produce increased light, and the same effect will be produced at c, c', and at all the intersections of the continuous arcs, where the difference in length of the rays proceeding from the points s, s' is equal to any multiple of λ or to any even multiple of $\frac{\lambda}{2}$. But at n, n' or any other intersections of a continuous and a dotted arc, where the difference in length of the rays sn, $s'n$, &c., is equal to $\frac{\lambda}{2}$, or any odd multiple thereof, the rays are in opposite phases, so that their vibrations act against one another, and the amount of light at those points is less than it would be if only one of the rays arrived there. The distance between the points s, s' being very small compared with Aa, the surface anc is very nearly plane, so, that if a white screen be placed there, a succession of luminous points, a, c, c', &c., will be formed upon it separated by dark spaces, n, n', &c.

If the sources s, s', instead of being luminous points, are lines of light perpendicular to the plane of the figure, a series of alternate light and dark bands, or fringes, will be produced parallel to those lines.

The conditions essential for exhibiting these effects are, that the two luminous sources s, s' shall be very near one another, and that the waves emanating from them shall always be simultaneously in the same phase. These conditions are most easily fulfilled by the following arrangement devised by Fresnel:—

A beam of light entering through a rectangular slit in the shutter of a darkened room, and passing through a plate of red glass, is condensed at S to a very fine line of light, by a cylindrical lens L (*fig.* 646) of very short focus. The rays there cross each other, and fall upon two plane mirrors Im, Im', placed together at a very obtuse angle, and having their line of intersection parallel to the line of light. The rays, after reflection from these mirrors, proceed as if they had originally issued from two points s, s', situated symmetrically to the point S, behind each of the mirrors. The mirrors being

Digitized by Google

placed nearly in one plane, the points s s' are very close together, so that all the conditions are fulfilled for the production of light and dark fringes on the screen, as above described.

Instead of reflecting the light diverging from S from two plane mirrors, it may be made to pass through a glass prism having a very large refracting angle. The fringes also, instead of being received on a screen, may be viewed through a telescope, and their angular breadths estimated by micrometrical measurement.

If the beam of light proceeding from one of the points s, s', be intercepted, the whole of the fringes disappear, and the light from the other source produces a uniform illumination on the screen, plainly showing that the fringes are produced by the combination or interference of the rays proceeding from the two sources.

Measurement of the lengths of the waves of light.—The breadths of the fringes having been ascertained, as above described, an easy calculation gives the lengths of the waves of the particular light by which they are produced. In *fig.* 646, the length of the wave λ is equal to the distance sa. Now the curvilinear triangle asc may be regarded as a right-angled triangle, whose hypothenuse $ac = b$ is the distance from the centre to the first bright lateral fringe. Moreover, the angles sca and sas' = ω are equal, because their sides are respectively perpendicular to one another: hence

$$\lambda = b \sin \omega.$$

Hence to obtain the value of λ, it is sufficient to measure the angle sas' with a repeating circle, and the distance ac with a micrometer. A more exact mode of determination will be described hereafter.

The length λ is proportional to the distance ac. Now the breadth of the fringes is found to be greatest in red and least in violet light, and of intermediate breadths for the intermediate colours of the spectrum: hence also it follows that *the lengths of the waves are greatest in red and least in violet light.*

The formula $\lambda = \frac{v}{n}$, in which v is the velocity of light, and n the number of vibrations per second, shows that the vibrations are most rapid in violet, and least rapid in red light.

The length of the wave and the rapidity of vibration of the particles of the ether determine the colour of the light, just as the length of the sound-wave and the rate of vibrations of the particles of the air, determine the pitch of sound.

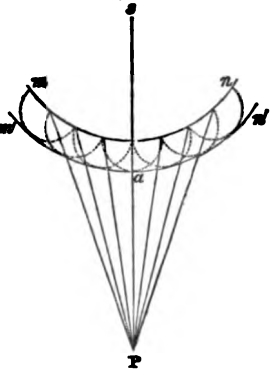
The following table exhibits the wave-lengths and the number of vibrations per second of the mean rays of the several colours of the spectrum, and of the principal fixed lines:

Fixed lines and colours.	Values of λ in ten-thousandths of a millimetre.	Number of vibrations per second in millions of millions.	Fixed lines and colours.	Values of λ in ten-thousandths of a millimetre.	Number of vibrations per second in millions of millions.
Line B . .	6·88	. .	Mean green .	5·12	601
Line C . .	6·56	. .	Line F . .	4·84	
Mean red .	6·20	497	Mean blue .	4·75	648
Line D . .	5·89	. .	Mean indigo .	4·49	686
Mean orange .	5·83	528	Line G . .	4·29	
Mean yellow .	5·51	529	Mean violet .	4·23	728
Line E . .	5·26	. .	Line H . .	3·93	

The expression $b = \frac{\lambda}{\sin \omega}$, which gives the breadth of the fringes in terms of the wave-length and the angle ω, shows that for each colour they are broader in proportion as that angle is smaller. If it is too large, that is, if the distance $s\,s'$ is too great in proportion to $A\,a$, the fringes disappear altogether; they are still visible, however, when this angle has a magnitude of several degrees.

The fringes being of different breadths in the different coloured lights, and white light, as will hereafter be shown, being a mixture of all the colours of the spectrum, it follows that when the preceding experiment is made with white light (sun-light, the electric light, or the lime-light), the bands produced are not simply bright and dark alternately, but exhibit a succession of colours produced by the combination of the simple colours in various proportions, and not separated by any absolutely dark bands. Moreover, these coloured fringes are much less numerous than the simple light and dark bands produced by homogeneous light, because the breadths of the simple-coloured fringes of which they are composed do not vary proportionally to one another, as their distance from the centre increases; hence, they ultimately become

Digitized by Google



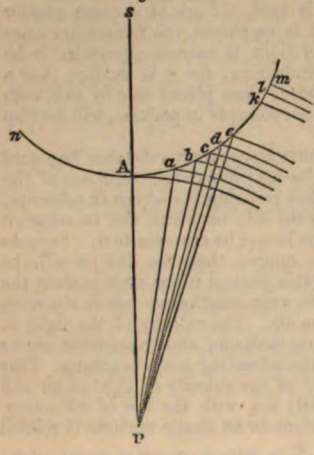
mixed, and reproduce white light. Even the simple fringes formed in homogeneous light become less and less distinct as they recede from the centre, and ultimately disappear when the difference between the lengths of the rays which form them becomes equal to a certain number of half-undulations. The cause of this disappearance is, that the light used in the experiment is never absolutely homogeneous, and that the want of perfect equality between the lengths of the waves which compose it, ultimately makes itself perceptible, the fringes of different breadths overlapping and effacing each other in the same manner as when white light is used, though at a much greater distance from the centre. Whatever kind of light is employed, the fringes are more distinct and numerous in proportion as the line of light is narrower, provided it be wide enough to give the required amount of illumination; for it is evident that a broad aperture may be regarded as a number of narrow ones placed side by side, each producing its own set of fringes, which, as they do not coincide in position, will overlap and efface each other more or less completely.

If a very thin plate of glass, mica, selenite, or other transparent substance be placed in front of one of the mirrors (*fig.* 646), so that the rays proceeding from one of the points, *s*, *s'*, shall be obliged to pass through it before reaching the screen or telescope, the whole of the fringes will be displaced towards the side on which the transparent plate is situated, so that the central fringe *a* will no longer be opposite to A. Suppose the displacement to be towards the right of the figure; then the line *s'a* will be shorter than *sa*. Now, as the two rays forming this central fringe must contain the same number of wave-lengths, it follows that these wave-lengths are less in the more highly refracting substance (glass, &c.) than in the air. The velocity of the light is, therefore, diminished in the more highly refracting medium; and experiment shows that the retardation thus produced is greater as the refracting power is greater. This result is in accordance with the direct measurement of the velocity of light in air and water (p. 595), and likewise, as we shall presently see, with the law of refraction. Moreover, as the velocity of transmission of vibrations in an elastic medium is related to its elasticity and density by the equation $v^2 = \frac{e}{d}$, it follows also that the elasticity of the ether is least, or its density greatest, in the most highly refracting media.

The transparent plate used in the experiment just described must be extremely thin; otherwise the fringes will disappear altogether, just as if an opaque screen had been interposed. A thicker plate would, in fact, shift the fringes beyond the space in which the two systems of waves meet each other, namely, the space bounded by the two straight lines passing through *s*, *s'* and the intersection, I, of the mirrors.

Diffraction. The principle of interference serves to explain some very remarkable and beautiful phenomena which are observed when light passes by the edge of an opaque body, or through a small aperture. The effects thus produced consist in this, that the light bends to a certain extent within the geometric shadow bounded by straight lines drawn from the luminous point through the edges of the opaque body, just as a wave in water will turn the angle of a wall, or spread itself through a hole in any fixed obstacle. The result is the formation of a number of alternate bright and dark bands or coloured fringes, sometimes within the shadow, sometimes beyond it, sometimes in both places at once. These effects, formerly known as Inflection, but now called Diffraction, admit of complete explanation on the wave-theory of light, but are quite inexplicable on the theory of emission.

Fig. 647.



The explanation of diffraction on the undulatory theory depends upon the general principle first enunciated by Huyghens, that—*The vibrations of a wave of light, at each of its points, may be regarded as the resultant of the elementary movements which would be communicated to it, at the same instant, by all the parts of the same wave in any one of its previous positions.* For it is evident, from the elasticity of the ether, and the facility with which vibratory movements are transmitted through it, that its particles do not vibrate independently of each other, but that each may be regarded as a centre of disturbance with regard to all around it. Consequently, each point of a spherical wave, *mn* (*fig.* 647), will produce by its vibration, a number of secondary spherical waves, which, spreading out with the same rapidity, will have for their enveloping surface—that is to say, for the general surface of the wave as it spreads outwards—another spherical surface, *m'n'*, concentric with the former. Hence the vibration imparted to any point P, by the wave *mn*,

Digitized by Google

when it reaches that point, may be regarded as the resultant of all disturbances emanating from the several points of *mn*.

To determine the manner in which the movement of P is affected points of the wave in any of its previous positions, draw *s*P, cutting the (*fig.* 648), and designating the distance AP by γ, describe, from P a with the radii γ, $\gamma + \frac{1}{2}\lambda$, $\gamma + 2.\frac{1}{2}\lambda$, a number of arcs cutting the wave *a*, *b*, *c*, *d*, . . . and draw the str Pb, Pc, &c., which evidently diffe by half a wave-length. Then it wi the intervals A*a*, *ab*, &c. are not tinually diminish from A toward for every point in *ab*, there exists such that the lines drawn from th differ by $\frac{1}{2}\lambda$, and consequently the w from these points to P will be in co ance. Hence, if A*a* were equal t on P would be completely neutrali this not being the case, *ab* can part of A*a*, and there remains a po A*a*, which produces a certain degr tion at P. There is a further reas tralises only part of A*a*, and that more obliquely. Similarly, *cd* w part, but only a part, of the action it will be seen that the illuminati P by the half-wave A*m* is the sum the arcs of uneven order over order, counting from A. In all ca

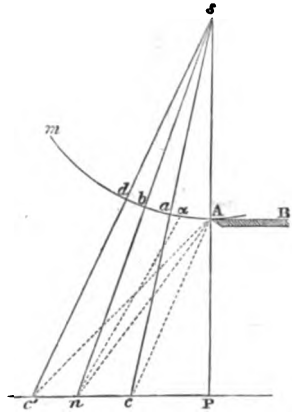
Fig. 648.

is only necessary to take account of that part of the wave which is v line *s*P: for at a greater distance, as at *m*, the arcs *kl*, *lm* become ve and, moreover, their action on P is very oblique—for both of whic effect on P may be neglected. The arc A*n* acts exactly like A*m*, illumination produced by A*m* be denoted by 1, that of the entire w equal to 2.

The arcs A*a*, *ab*, &c. are called elements of interference, and called the pole of the point P.

The direction of vibration of the ether-molecule P at any instant is that of the first element A*a*, of the half-wave A*m*; and if this portion w the point P would then vibrate in the direction determined by the n which is opposite to that of A*a*. Hence, it appears that the action of A*a* than the resultant actions of all the remaining elements, *ab*, *bc*, &c.: for changes its direction according as the element A*a* acts upon it or not, true with regard to each of the elements *ab*, *bc*, &c., the action of ea on P being greater than the resultant of all beyond it.

Now, suppose part of the half-wave A*m* to be intercepted by the int opaque screen; then the arc *ab*, which destroyed a great part of the removed, and the point P receives more light than it did before: for is greater than that of all the rest of the wave, from *b* outwards, ta Next suppose the screen to terminate at *b*; then, since *ab* destroys the A*a*, and the rest of the wave is intercepted, P will now receive less ligh if the screen were not there. In the same manner, it will be found th screen is so placed as to leave an odd number of elements of the wav P will be more illuminated than it would be if the screen were not contrary if an even number are left free.



These principles lead immediately to the explanation of the phenome

1. *Fringes produced by rays passing along the edge of a screen.*—S of homogeneous light proceeding from a luminous point S (*fig.* 649) a fine line of light passing through S at right angles to the plane of th by the opaque screen AB, of indefinite extent towards B, and fall upon CD, covered with white paper. The boundary of the geometrical determined by the straight line SAP. The light received at P will p half-wave A*m*, and may be represented by 1; and from the preceding follows that the points *c*, *c'*, &c., so situated that $Ac - ac = \frac{1}{2}\lambda$; Ac' receive more light than if the screen were not there, and will therefor of bright fringes; and on the contrary, the points *n* *n'*, &c., for whi

Digitized by Google

$As' - b'n' = 2\lambda$, &c., will receive less light than if the screen were away, and will therefore be the centres of dark fringes. The general result may be thus stated: The presence of a screen increases the intensity of the light at every point so situated that the broken line (SA, A*c* for example) passing to it from the source of light by the edge of the screen exceeds the straight line (S*c*) drawn to it directly from the luminous source, by an *odd* number of half undulations, and diminishes the intensity of the light at every point so situated, that the broken line (SA, A*n*) proceeding to it from the luminous point by the edge of the screen, exceeds the straight line joining it with the luminous point, by an *even* number of half-undulations.

Fig. 649.

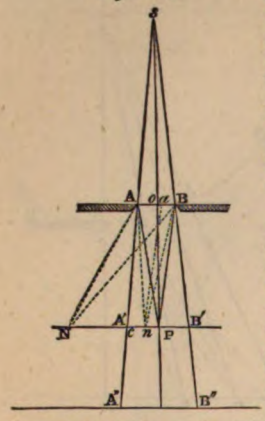
In this manner, a succession of bright and dark fringes are produced beyond the geometrical shadow of AB; they may either be received on the screen CD, or viewed by a telescope directed to the edge A, the latter being of course the better method for exact measurement. They become less and less distinct as their distance from the edge of the shadow increases, because the successive arcs A*a*, *ab*, *bd*, &c. do not neutralise each other's action completely, so that a small quantity of light always mixes with the dark fringes, increasing in amount as they are more distant from P. Finally, at points situated so far from P that the portion of the half-wave intercepted by the screen is too far from the pole *b'* to produce a sensible effect, the fringes disappear altogether, and the surface of the screen becomes uniformly illuminated with light of intensity = 2.

The fringes are broadest in red, and narrowest in violet light; and in white light fringes of compound colours are formed, as in the experiment with the mirrors.

The locus of each fringe, light or dark, considered at different distances from the luminous source, is a hyperbola, having the points A, *s* for its foci. The dark fringe *n*, for example, of the *m*th order, gives $An - bn = m.\frac{1}{2}\lambda$; and subtracting these equal magnitudes from $sb = sA$, we have $sb - An + bn$, or $sn - An = sA - m.\frac{1}{2}\lambda$. The difference $sn - An$ is therefore constant, whatever may be the length of AP; consequently, the locus of the point *n* is a hyperbola whose foci are A and S.

There is also a certain quantity of light *within the geometrical shadow*. For any point *p* situated to the right of P (*fig.* 649) receives light from a certain portion of the wave A*ab*; but this portion is smaller and farther from the corresponding pole, as *p* is more remote from P: hence the brightness of the light diminishes rapidly from the edge of the shadow inwards; but the diminution is continuous and no fringes are produced.

Fringes at the edge of a Mirror.—Rays reflected from the edge of a plane mirror inclined to their direction, proceed as if they had originally issued from a line of light situated symmetrically behind the mirror. The space beyond the mirror may therefore be compared to the opaque screen in the experiment last described: hence the fringes are produced towards the surface of the mirror, whilst a continuous light is visible for a short distance beyond it.



2. *Fringes produced by narrow rectangular apertures.*—Light passing through such an aperture may form fringes in the beam of light itself and in the shadow, separately or together, according to the width of the slit and the distance at which the fringes are viewed. They may be observed by means of a very simple apparatus, consisting of two thin plates of copper fixed in a small frame, one of them being capable of sliding backwards and forwards, so as to vary the width of the aperture at pleasure. On looking at the flame of a candle or other source of light through the slit, brilliant coloured fringes are seen parallel to the edges of the slit. These fringes are also very distinctly seen on viewing the flame of a candle between two fingers held up so as to leave a very narrow space between them.

Internal Fringes.—Let AB (*fig.* 650) be the slit, S the source of light, rendered homogeneous by passing through a coloured glass; and suppose in the first place that the screen A'B', on which the light is thrown, is placed at such a distance that $AP - oP$ and $BP - oP = \frac{1}{2}\lambda$; then all the points of the part AB of the wave-surface will be in accordance with each other, and there will be a bright band at P. The same will be the case *a fortiori*, if the screen A'B' is still farther removed, as to A"B". But if the screen be moved to a shorter distance from the slit, such that $AP - oP$ is

External Fringes.—The mode of production of these fringes is similar
internal fringes just considered. Any point N, within the shadow on ei

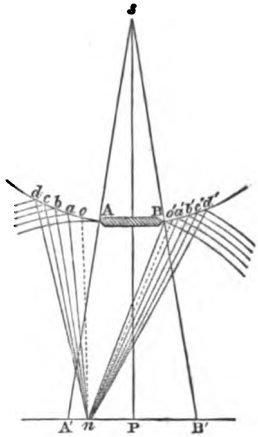
an odd number of times $\frac{1}{2}\lambda$. These external fringes rapidly lose their disti
recede from the edge of the geometric shadow, and disappear altogether
is so wide that the vibrations emitted from the point B are no longer s
For the simultaneous production of external and internal fringes, therefor
must be neither too wide nor too narrow.

The loci of both the external and internal fringes are hyperbolas ha
in A and B. All the fringes are broadest in red and narrowest in viole
white light are made up of bright bands of various colours.

3. *Fringes produced by two narrow slits very close together.*—The two
interfere and produce fringes, precisely as in Fresnel's experiment with
This, which is Young's form of the experiment, is similar to that by w
originally showed that light added to light may produce darkness.



4. *Fringes produced by very narrow screens.*—In this case also fringes
both within and without the shadow. A hair or a thin wire held between t
flame of a candle or a bright line of light, exhibits these fringes very distin
that the screen A B, instead of being of indefinite extent towards B, as in
narrow that the light passing by each of its edges A, B (*fig.* 651), goe
middle of the geometric shadow A'B'; the rays will then act upon each
produce fringes within the shadow, independently of those beyond it.
also modified, because the points at which they are formed likewise rece
the opposite edge of the narrow screen, which contributes to their forma
on interposing an opaque body so as to cut off the light from one edge
the external fringes immediately alter their appearance, and the interna
pear altogether.

Formation of the internal fringes.—If the screen AB (*fig.* 651) is
narrow, the internal fringes differ but little from those which would
two slits placed at A and B; for the direction of vibration at any point
shadow is then determined by the action of the two elementary portio
immediately contiguous to A and B. When the screen is extremely nar
is the same, excepting that the effect of the first elements of interference
arcs Ad, Bd', being modified by the other portions of these waves, whic
tralise their action, the points, o, o', from which the resultant actions o

Digitized by Google

may be considered as proceeding, are situated somewhat closer to A and B than they would be if the portions of the wave beyond *a* and *a'* were cut off. At any point *n* within the shadow, there will be a light or a dark band (in homogeneous light), according as $o'n - on$ is equal to an odd or even number of half-undulations. The point P in the middle of the geometric shadow, being perfectly symmetrical with regard to the arcs *Ad*, *Bd'*, receives from them accordant impulses, and is therefore the centre of a bright band.

Fig. 651.

The fringes are wider apart in proportion as AB is smaller, because in order, to obtain a given difference of length in the rays *on*, *on'*, the point *n* must then be taken farther from P. This may be verified by viewing a needle held parallel to a bright line of light; the fringes are then much broader near the point than near the eye.

5. *Fringes produced by screens or apertures which are very small in all directions.*—The effects in this case are much more complicated than in those above considered, where the edges of the screen or aperture are supposed to be straight, and so much elongated that it is sufficient to consider the effect of the cylindrical wave situated in a section at right angles to the screen or aperture. But in the case now under consideration it is necessary to consider the actions resulting from all the points of the free surface of the wave, and the problem becomes too complicated to be treated without the aid of the higher analysis. We shall therefore merely enumerate the effects produced in a few of the more simple cases.

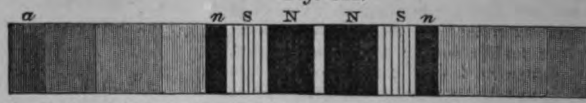
When rays proceeding from a luminous point pass through *a small circular aperture* circular fringes are formed, both within and beyond the geometric image. The circular aperture may in fact be regarded as a number of very narrow rectilineal apertures radiating from the centre. In homogeneous light the rings are equidistant, and their diameters are inversely as that of the aperture, excepting that the distance from the centre to the first ring is less than that between two consecutive rings. The centre is bright or dark, according to the proportion between the size of the aperture and its distance from the screen, and either the external or internal rings may disappear according to these dimensions.

A small circular screen also produces fringes similar to those of the linear fringes formed by a narrow rectangular screen. At certain distances, the centre of the shadow is as bright as if the screen were not there.

A small rectangular aperture forms two series of fringes at right angles to its sides; their distances being inversely as the widths of the aperture in all directions. There is also a great number of small spectra, regularly distributed in the angular spaces formed by the two series of fringes.

Two small circular apertures placed at a certain distance from one another, form two series of rings just as if each of them existed alone; but if they are close enough to make the rings overlap, the rays proceeding from the two likewise produce, by their interference, a series of very close rectilineal fringes at right angles to the line joining the centres of the apertures, together with two sets of oblique fringes passing through the middle point between these centres. This is the original experiment of Grimaldi already referred to (p. 604).

6. *Diffraction through Gratings or Networks.*—When light, instead of passing through one or two small apertures, passes through a great number of them very close together and regularly distributed, some very remarkable diffraction phenomena are produced, which were discovered by Fraunhofer. Such a system of apertures is called in optical language a grating (*réseau*, Fr.; *Gitter*, Germ.).



Fraunhofer formed his gratings:—1. By winding a very fine wire round two parallel screws of equal diameter and very fine thread.—2. By tracing very fine parallel lines on a film of gold-leaf fixed on a plate of glass.—3. By tracing lines with a diamond on a plate of glass, the lines thus formed being opaque, while the intermediate spaces are transparent. This is the method now generally adopted, a dividing engine being used to ensure regularity in the lines. Sometimes the lines are traced on glass covered with a thin coat of varnish, and etched with hydrofluoric acid. When great regularity is desired, the number of lines in a millimetre must not exceed 300, and 38 in that space are sufficient for the complete manifestation of the phenomena.

Effects of Parallel gratings.—A line of light viewed through a grating formed by parallel lines, appears just as it would to the naked eye, excepting that it is somewhat

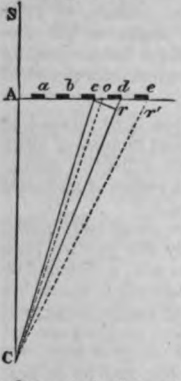
distance from the grating.



By observations thus made it is found that:—1
points of the successive spectra are equidistant, or in other words, the
these middle points are to one another as the numbers 1, 2, 3, 4, &c.

2. The lengths of the successive spectra, or the distances between two
responding fixed lines, are to one another as the same numbers.

3. The difference of thickness of the opaque and transparent lines has
on the position of the spectra, but merely modifies their brightness.

4. The lengths of the spectra depend upon the sum of the widths of ar
transparent space taken together; this sum is called an element of

there. But at a certain distance A*d*, such that an opaque line of the gra

Digitized by Google

covers the element of the wave which would counteract the action of the preceding element, light will be seen in the direction C*d*, the distance A*d* being greater in proportion as the eye is farther from the grating. If, for example, the angle AC*d* is of such a magnitude that $dC - oC = oC - cC = \frac{1}{2}\lambda$ of the violet, the vibrations communicated to the point C by the element *co*, will not be destroyed by *od*, and violet light will be seen in the direction C*o*, brighter in proportion as the edge of the dark space is nearer to *o*.

To calculate the deviation $dCA = d$, describe the arc *cr* having its centre at C; the triangle *dcr* gives $dr = \lambda = \overline{cd} \sin d$; and supposing *cd* to be contained N times in a millimetre, we have then $1 = N.\ \overline{cd}$, and the preceding equation gives $\sin d = N\lambda$, or taking the angle for the sine, $d = N\lambda$, which is in fact the general formula of the diffraction-spectra ($D = mk N$) applied to the case of the first spectrum. It shows that the deviation is independent of the difference between the opaque and the transparent spaces, and that the constant k is the length of an undulation corresponding to the colour under consideration. For the other colours, we find in like manner $d' = N\lambda'$, $d'' = N\lambda''$, &c., λ being greater λ, and λ'' greater than λ' &c. The colours will therefore appear one after the other, at angular distances sensibly proportional to λ, λ', λ'', &c.

Consider, in the next place, another element of the grating at such a distance from A that the difference $dC - cC = 2\lambda$, or in general to $m\lambda$, m being a whole number. The interval may then be divided into $2m$ elements of interference corresponding to differences of distance from C, equal to $\frac{1}{2}\lambda$, and these elements being of even number, the actions resulting from their several points would counteract one another two by two, if there were no opaque spaces. But if the opaque spaces cover an *uneven number of elements*, so that an uneven number also remains free, one of these latter will act unopposed, and there will be light in the corresponding direction. The triangle *cdr*, then gives $d = m\lambda N$, which is the general formula above given.

It remains to be seen why the light of any particular colour is wanting between the luminous band which corresponds to the difference of distance $m\lambda$ from C, and that which corresponds to $(m + 1)\lambda$. Now between the lines of the grating corresponding to these two bands, two zones may be found in which the differences of distance from the point C increases from $m\lambda$ to $m\lambda + \frac{1}{2}\lambda$, then from this latter to $m\lambda + 2 . \frac{1}{2}\lambda = (m + 1)\lambda$. The rays emanating from the corresponding points of these two zones differ in length of path by $\frac{1}{2}\lambda$, and destroy one another on reaching the point C. Dark bands will therefore occur in the direction of these zones. In white light, however, the colours, by overlapping one another, obliterate all these dark bands, excepting the first two on either side.

If the source of light is too near the grating to allow the rays to be regarded as parallel, the same mode of explanation is still applicable, only it becomes necessary to take account of the difference of path of the contiguous oblique rays at the moment when they reach the grating.

The formula $\sin d = m N\lambda$, shows that when $N\lambda$ is greater than 1, that is to say when $\frac{1}{N}$, or an *element* of the grating, is less than λ, $\sin d$ becomes greater than 1, which is impossible; in this case therefore no spectra can be formed, and in fact gratings which have their bars too close do not form any.

If the spectra are observed in any other medium, as when the slit and grating are placed at the opposite ends of a tube filled with water or other liquid, then, if l is the length of an undulation of violet light in that liquid, the deviation will be $d_1 = N\lambda$, which combined with the equation $d = N\lambda$, for the deviation of the same part of the spectrum in air, gives $d_1 : d = l : \lambda$, which is the ratio of the indices of refraction in the medium and in air.

Measurement of λ. The equation, $\sin d = N\lambda$, gives the means of measuring with great accuracy the wave-lengths corresponding to the several fixed lines of the spectrum, which cannot be done with the interference-fringes in Fresnel's experiment (p. 599), because the lines are not distinct. It is by this method that Babinet determined the values given in the table on p. 600.

Irregular Gratings.—Gratings whose bars are totally destitute of regular arrangement produce nothing but a whitish train of light at right angles to the bars: but if the irregularities are subject to a certain law and recur periodically, spectra are produced, whose deviation is expressed by the formula $\sin d = \frac{m\lambda}{L}$, in which L denotes the space comprising one complete set of bars. The successive spectra then differ greatly in brightness; some are very pale, and, occurring by the side of very bright ones, partly overlap them, but do not perceptibly alter their colours: hence lines may be distinguished in some of these spectra of the higher orders, which cannot be seen in the spectra of the correspond-

Reflecting Gratings or Striated Surfaces.—When light is reflected fr
covered with striæ alternately bright and dull, the same spectra are produ
it is transmitted through a grating: for the reflected rays are in the sam
they had been transmitted through the striated surface from a point as f
the actual luminous point is before it; the spectra are not, however, quite
those produced by transmission. The iridescence of mother-of-pearl is
very fine striæ resulting from its foliated structure; a cast taken of it
mastic, or fusible metal, exhibits a similar iridescence. Fibrous gyps
colours due to the same cause. The feathers of certain birds likewise ow
liant colours to diffraction of the light reflected from the very fine filame
they are composed.

Half-polished metals sometimes exhibit iridescent colours, due to the p
produced by the hard powder used in polishing them; but as these stri
regular, the usual effect is merely a whitish line of light, at the points fro
rays are reflected to the eye. *Barton's buttons*, which are metallic but
very fine lines engraved on their surfaces by a peculiar machine, exhibit
diffraction spectra.

Reflection and Refraction.

When a wave of light reaches the surface of separation of two media
densities, its vibrations are not only propagated onwards into the second
likewise reflected back into the first, each particle of the ether at the surfa
tion then becoming a centre of disturbance from which fresh waves spre
directions. To find the directions of the reflected and transmitted wa

to sa and en'; then a vibration of the ray sa, in reaching the surface ab, will have travelled over a space greater by $a\alpha$ than the corresponding vibration of the ray te: but when the two arrive at the surface $a\beta$ of the refracted wave, te will have moved over a space which, expressed in wave-lengths, is greater, by $\mu . e\beta - a\alpha$, than that passed over by sa. Let i be the angle of incidence, αea, and ρ the angle of refraction, $ea\beta$, of the ray an. Then the right-angled triangles $e\beta a$, eaa give $e\beta = ae . \sin \rho$; $a\alpha = ae . \sin i$; therefore $\mu . e\beta - a\alpha = ae (\mu . \sin \rho - \sin i)$; and $ae = \frac{\mu . e\beta - a\alpha}{\mu . \sin \rho - \sin i}$. Now the rays an, en' will destroy one another by interference when the difference $\mu . e\beta - a\alpha = \frac{1}{2}\lambda$; therefore, when $ae = \frac{\frac{1}{2}\lambda}{\mu \sin \rho - \sin i}$. This shows that ae is smaller, or the interfering rays are closer together, the more the ratio $\frac{\sin i}{\sin \rho}$ differs from μ; but when it is equal to μ, that is, when the refracted ray is in the direction indicated by the law of the sines, ae becomes infinite, and therefore there is no interference.

A precisely similar construction and demonstration, applied to the reflected rays an'', en''' (*fig.* 655), shows that the contiguous reflected rays destroy each other in all

Fig. 655.

cases excepting when $\sin \rho = \sin i$, that is to say, when the reflected and incident rays make equal angles with the normal. If, however, the point a is very close to the left-hand edge of the mirror, the reflected ray en' will not exist, and an will not be destroyed. Hence if the mirror is very narrow, the rays reflected obliquely to the beam $rabr'$ are not completely destroyed, and the reflected beam becomes divergent. Fresnel verified this theoretical deduction by blackening the surface of a mirror, with the exception of a very narrow triangular space. The beam of light reflected from this space was broadest at the narrowest part of the reflecting surface, so that the image which it formed on a screen was a triangle with truncated summit, in a position the reverse of that of the reflecting triangle.

The reflected and refracted beams are always less bright than the incident beam. In fact, they would be together equal in intensity to the incident beam, were it not that part of the light is scattered in all directions, by reflection from minute irregularities on the surface of the medium; and secondly, that a portion of it, often very considerable, is apparently lost by absorption. This process doubtless consists in a communication of the vibratory motion of the ether to the particles of the ponderable body itself, the particles thus set in motion again acting as centres of vibration, and exciting fresh undulations in the surrounding ether, thereby rendering the body visible. The vibrations excited in the particles of a ponderable body by the movements of the ether likewise produce numerous changes in the state of the body itself, raising its temperature, and setting up certain chemical actions within it, which will be afterwards more fully considered. It is true that the ether transmits vibratory movements which render bodies hot, and others which determine chemical changes

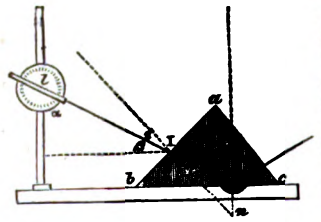
should be parallel. As, however, this condition filled, it is necessary to measure the deviatio when empty, previous to making the observat examined. The first deviation is then to be d the second, according as it is in the same or in

As liquids are very expansible by heat, thei be sensibly affected, even by variations of temperature not e rounding atmosphere. It is necessary, therefore, to make the temperature, to agitate the liquid briskly before making the using the direct rays of the sun, which might heat it unequal

2. *By total reflection.*—This method is especially applicabl of liquid; also to imperfectly transparent liquids and past crystalline lens of the eye. A small drop of the liquid is att of a right-angled prism BAL (*fig.* 660), resting on a horizo hole o is made to rece must be formed of a su tive index, greater than drop of liquid is viewe means of a small tel centre of a graduated down a vertical rule L telescope is at first fix objects below the drop on gradually lowering angle Ion continually i rays coming from the at m are totally reflec observed. The angle

Fig. 661.



is then fixed, and the angle α is the limiting angle θ, and $\sin\theta = \frac{\mu'}{\mu}$, μ being the refractive i that of the liquid. Now the angle $\theta = 90° - r$; therefore $\mu \cos\theta$; hence $\cos\theta = \frac{\cos\alpha}{\mu}$, and $\sin\theta = \frac{1}{\mu}\sqrt{\mu^2 - \cos^2\alpha} = \frac{\mu'}{\mu}$;

$$\mu' = \sqrt{\mu^2 - \cos^2\alpha}.$$

Wollaston devised a modification of this method by which th determined without cal

Fig. 662.

ments of Chemistry, 3r *Traité de Physique*, 2me trouble of calculation mula is not, however the method. A mo arises from the difficu exactly rectangular. T Malus uses an acute-an angle b of which is being made as above before, $\beta = 90° - \alpha$ a normal In be produced in n; then the angle n is equal to the angle b of the pris gives $\theta = r + b$; whence $\sin\theta = \frac{\mu'}{\mu} = \sin(r + b) = \sin r$ $\mu \sin r = \sin i$; and the triangle $In'n$ gives $n'In = i$ $i = 90° - (b + \beta)$: therefore

$$\sin r = \frac{1}{\mu}\cos(b + \beta);$$

and

$$\cos r = \frac{1}{\mu}\sqrt{\mu^2 - \cos^2(b + \beta)}.$$

This gives; $\mu' = \mu \sin\theta = \cos(b + \beta)\cos b + \sin b\sqrt{\mu^2 -$

This method may also be applied to solids. Soft bodi organic bodies may be at once attached to the lower surf

Digitized by Google

bodies may be attached by means of a liquid of *greater refracting power* than the prism: the total reflection will then take place just as if the solid were immediately attached.

The same method also gives the index of refraction of the prism itself, the observation being made without applying any liquid to the lower face. In this case, since the medium below the prism is air, we have $\mu' = 1$, and the formula gives

$$\mu = \frac{1}{\sin b}\sqrt{1 + \cos^2(b + \beta) - 2\cos b \cos(b + \beta)}.$$

The following tables contain the indices of refraction of several solids and liquids, determined by the preceding methods. They all relate to the yellow rays of the spectrum, excepting those of Wollaston, which relate to the extreme red:

Indices of Refraction of Solids.

The indices of refraction assigned to the same substance by different ob exhibit considerable diversities, arising partly from imperfection of meth cially from want of chemical or physical identity in the substances exami

A comparison of the indices of refraction of different substances lead general conclusions. One of the most remarkable is that inflammable s strongly refractive: *e. g.*, sulphur and phosphorus among solids; oils and among liquids; it was the observation of this fact that led Newton to i diamond would be found to contain an inflammable principle.

Generally speaking, the refracting power of *any one substance* increases sity; though it is by no means true that the refracting powers of different s proportional to, or even follow in the same order as their densities. Jami method presently to be noticed, that the refracting power of water is incr pression. On the other hand, the refracting power of liquids is diminish are expanded by heat. Brewster found that the index of refraction of c which, at ordinary temperatures, is equal to 1·358, is reduced to 1·057 whe of the ether is tripled by heat. Numerous experiments on this subject ha by Dale and Gladstone (Phil. Trans. 1858; Ann. Ch. Phys. [3] lv operated on twelve different liquids between the temperatures of 3° and method of minimum deviation. The prism was placed horizontally and spirit-lamp or cooled by a freezing mixture. The temperature was in thermometer with which the liquid was stirred. The following table conta of the results (see also page 625); they relate to the line D of the so excepting those with phosphorus, which relate to the line C:

Tempera-ture.	Sulphide of carbon.	Water.	Ether.	Alcohol, absolute.	Methyl-alcohol.	Phosphor liquid.
0°	1·6442	1·3330				
10	1·6346	1·3327	1·3592	1·3658	1·3379

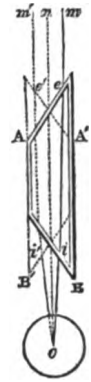
30	1·6182	1·3309	1·3495	1·3578	. .	2·0741
40	1·6103	1·3297	. .	1·3536	1·3297	2·0677
50	. .	1·3280	. .	1·3491	. .	2·0603
60	. .	1·3259	. .	1·3437	. .	2·0515

The refractive index of *water* diminishes continuously between − 1·3° the direction of the variation not changing in the passage through the point density. (Arago. Jamin. Dale and Gladstone.)

In the passage of a body from the solid to the liquid state, the refr sometimes diminishes, as in the case of *phosphoric acid*, *wax*, and *tallow*. it increases, as with *water* and *borax*; sometimes again it does not change as is the case with *sugar*.



H. Deville (Ann. Ch. Phys. [3] v. 129) has measured the index of *alcohol*, *wood-spirit*, and *acetic acid*, mixed with water in different proport substances exhibit the greatest degree of contraction, or of density, when uni water (*e. g.*, $2C^2H^6O.3H^2O$). It is also with this proportion of water tha and acetic acid exhibit the highest degree of refractive power, whereas this is the case when it contains ½ at. water ($2C^2H^6O.H^2O$). At 16° the dex of absolute alcohol is 1·3663; that of $2C^2H^6O.H^2O$ is 1·3662; that methylic alcohol, CH^4O, is 1·3358; of $2CH^4O.3H^2O$, 1·3462; that acetic acid, $C^4H^6O^3$, is 1·3753; and of $2C^4H^6O^3.3H^2O$, 1·3781.

Index of Refraction of Gases. Refractive Power. Biot and Arago the refractive index of atmospheric air, by the method of minimum devia hollow glass prism, called a *Borda's prism*, consisting of a glass tube (*fig.* centimetres in diameter, and having its ends *a*, *b* cut in a slanting directio with very thin plates of parallel glass. The prism was mounted, with its ref vertical, on a brass tube connected with a stop-cock and screwed on to th air-pump. The pressure of the air in the tube was measured by connect siphon-gauge. The tube having been exhausted, filled with dry air seven again exhausted, observations were made with it similar to those describ with this exception however, that as the refracting power of the exhauste less than that of the surrounding air, the *maximum*, instead of the *minim* was observed. The deviations being extremely small, the thickness of th vented the mark from being viewed directly. To obviate this difficulty, a had been viewed through the prism represented in section at AB, and t deviation of the ray *m e i o* observed, the prism was moved half round into

Digitized by Google

AB, and the same mark again observed. The image m was thereby thrown to the opposite side of the ray no proceeding directly from the object, so that the angle ios' was equal to twice the angle noi. This method gave for the index of refraction of air at 0° C. and 0·76 met. barometric pressure, referred to a vacuum as the unit, the number 1·00294.

Fig. 663.

In like manner, the indices of refraction of other gases were determined, referred to that of air as unity.

Now on measuring in this manner the refraction produced by air or other gases at different densities, it was found that, at pressures not exceeding that of the atmosphere, the quantity μ^2-1, which is called the **refractive power**, is proportional to the density of the gas—in other words, that $\frac{\mu^2-1}{d}$, which may be called the **specific refractive power**, is a constant quantity. The law was not verified for pressures greater than that of the atmosphere, on account of the difficulty of retaining condensed gases within the hollow prism.

Dulong determined the refractive powers of a considerable number of gases and vapours by the following method, founded on the proportionality of the refractive power to the density. A distant mark is observed by a telescope through a Borda's prism filled with dry air, at a pressure h. The prism and telescope are then fixed, and the prism is filled with another gas, the pressure of which is varied till the image of the mark again coincides with the wire of the telescope. The refractive index of the gas under the pressure h', is then equal to that of the air under the pressure h. If then μ' and μ are the indices of refraction of the gas and of air at the same pressure h, and at the same temperature, we have, since the index of the gas under the pressure h' is equal to μ,

$$\mu'^2-1 : \mu^2-1 = h : h',$$

whence μ' is easily found.

By this method Dulong has shown: 1. That the refractive power of a mixture of gases is equal to the mean of those of the constituent gases calculated for the pressure to which each gas is actually subjected in the mixture. 2. That the refractive power of a compound gas is not equal to the mean of those of the component gases, but is sometimes greater and sometimes less. The third column of the following table exhibits the differences *between* the actual refractive powers of certain compound gases, and those which would be obtained by adding together the refractive powers of the several components, and dividing by the volume of the compound gas. The refractive power of atmospheric air is found to be exactly the mean of those of its two constituent gases, a fact which shows, together with others, that the air is a mixture, and not a compound of oxygen and nitrogen.

The numbers in this table show that there is no simple relation between the refractive powers of different gases and their densities; hydrochloric acid gas, for example, has a lower density, but much higher refractive power than sulphurous anhydride, and ether-vapour has about the same density as chlorine, but double the refractive power.

The interferential method, the principle of which has been already described, is very well adapted to the measurement of the refractive indices of gases, and gives results more exact than those of the preceding methods. Arago and Fresnel applied it to the comparison of the refractive indices of moist and dry air. The interfering rays were made to pass through two copper tubes, each a metre in length, and closed at the ends with glass plates having exactly parallel faces, the one being filled with moist and the other with dry air. The fringes were then found to be displaced to the amount of one band and a quarter on the side of the dry tube, showing that moist air is rather less refractive than dry air. *Precipitated vapour* was found to produce a very slight increase in the refracting power of the air.

An improved apparatus for experiments of this kind has been constructed by Jamin, but we must refer for the description of it to his memoir (Ann. Ch. Phys. [3], xlix. 382), or Daguin's *Traité de Physique*, iv. 402. By means of this apparatus, Jamin has shown that vapour of water, at the temperature of 0° and at 0·76 met. barometric pressure, supposing it could exist under those circumstances, would have an absolute index of refraction equal to 1·00261, which is less than that of air at the same temperature and pressure. The refractive power of aqueous vapour calculated by the formula $\mu^2 - 1$ is therefore = 0·000521.

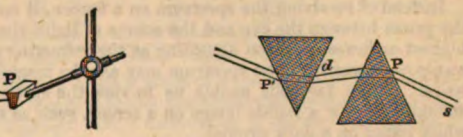
By adding to the refractive index of dry air that of aqueous vapour in the saturated state, under the pressure which it possesses at 20°, Jamin finds that the difference between the refractive indices of dry air and air saturated with aqueous vapour is only 0·000000726, a quantity which is too small to produce any sensible effects with Borda's prism, and may be safely neglected in the calculation of atmospheric refraction for astronomical purposes.

Refractive power of vapours produced at high temperatures. Leroux (Ann. Ch. Phys. [3], lxi. 385) has measured the refractive indices of a few of these vapours by the method of least deviation, using a hollow prism of iron having part of its opposite faces replaced by flat glass plates, and provided with proper appliances for heating, and for keeping the pressure of the vapour equal to that of the atmosphere. The indices and refractive powers of the vapours examined are as follows:

Substance.	Absolute index of refraction.	Refractive power $\mu^2 - 1$.
Sulphur . . .	1·001629	0·003258
Phosphorus . .	1·001364	0·002728
Arsenic . . .	1·091114	0·002228
Mercury . . .	1·000556	0·001112

Dispersion.

When a narrow beam of the sun's rays is passed through a glass prism (*fig.* 664) and received upon a screen, an elongated image or spectrum is formed, exhibiting a series of brilliant colours in the following order:



Red. Orange. Yellow. Green. Blue. Indigo. Violet.

the red occupying the lowest or the highest place, according as the refracting angle of the prism is turned downwards or upwards. The different coloured rays are therefore refracted by the prism in different degrees, the red exhibiting the least, and the violet the greatest deviation. Moreover, if a small hole be made in any part of the screen so as to allow a narrow beam of the rays of any one colour to pass, and this beam be transmitted through another prism, it will not again be elongated and split up into

f light must not be divergent, and the apparent dia-
which the light proceeds must be as small as possible·
ough a very small aperture is more divergent as the
of light is larger; the sun's rays passing through such
a vertical angle of 30 minutes. Newton obtained a
very bright and pure spectrum by passing a broad and thick rectangular beam of light through a convex lens L (*fig.* 666) of long focus, placed very near the prism P, and receiving the light on a white screen placed in the focus of the lens. Each colour is then brought to a focus on the screen, forming a bright narrow spot, the whole producing a very pure spectrum *rv*. An improvement on

To obtain a beam of perfectly homogeneous light, a coloured beam passing through a small hole in the part of the screen on which the spectrum produced as above is received, is transmitted through a second prism; and if the deflected image thus formed is at all elongated, showing that the original coloured beam was not quite homogeneous, the light of a portion of it must be passed through an aperture in a second screen placed to receive it. A ray thus separated will be found to be perfectly homogeneous in colour, and of uniform refrangibility.

Instead of receiving the spectrum on a screen, it may be viewed directly by holding the prism between the eye and the source of light, the red rays then appearing in the highest or lowest position according as the refracting angle of the prism is held downwards or upwards. The spectrum may also be magnified by viewing it through a telescope. These methods enable us to view the spectra of sources of light not bright enough to throw a visible image on a screen, such as the light reflected from a strip of white paper on a dark ground.

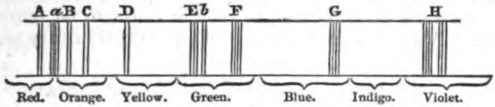
The spectra of the moon and planets, and of white terrestial objects illuminated by solar light, are similar to that obtained with the direct rays of the sun. The spectra of the fixed stars exhibit the same colours and nearly in the same proportions. Those of ordinary flames (hydrocarbon flames) likewise exhibit the same colours, but with a larger proportion of yellow. That of an alcohol flame consists mainly of yellow light, and if a little common salt be mixed with the alcohol, the flame gives a perfectly monochromatic yellow light. The flame of a Bunsen's burner in which a salt of lithium is ignited, gives a spectrum consisting almost wholly of red light; and when a salt of thallium is ignited in it, the spectrum consists wholly of green light.

Fixed Lines in the Solar Spectrum.

Newton, by passing a beam of light proceeding from a small circular aperture through a prism, obtained a spectrum which appeared perfectly continuous, whence he concluded that white light contained rays of all degrees of refrangibility, regularly increasing from the red to the violet. But Wollaston in 1802, by looking through a good flint glass prism at a very narrow rectangular aperture illuminated by sun-light, perceived that the spectrum was intersected by several very fine dark lines parallel to the edges of the prism, or to the boundary lines of the several colours; and fifteen years afterwards, Fraunhofer of Munich, without being acquainted with Wollaston's observations, made the same discovery by viewing a spectrum formed in the manner just described through a telescope. The lines were very fine, all dark, and some perfectly black, and Fraunhofer was able to count between 500 and 600 of them, their number increasing with the magnifying power of the telescope. These lines are distributed irregularly throughout the whole length of the spectrum, and do not, for the most part, occur at the limits of the principal colours. Eight of them, easily distinguished by their position and intensity, are denoted by the first eight letters of the alphabet, beginning from the red of the spectrum: they are shown in *fig.* 667. Some of them, when examined by a good magnifying power in a well-developed spectrum, are resolved into a number of fine lines very close together. There are two more groups of lines which are particularly conspicuous, one denoted by *a*, consisting of eight fine lines in the red between A and B, and another *b* in the green near E, consisting of three fine lines, the two stronger of which are separated by a bright space.

These dark lines show that the solar spectrum is not continuous; in other words, that there do not exist rays of all degrees of refrangibility between the red and the violet.

The aspect, order, and relative distances of the lines in the solar spectrum remain the same, for a prism of given substance, whatever may be the magnitude of its refracting angle; but if the substance of the prism be changed, the relative distances of the fixed lines and the relative widths of the several coloured spaces are likewise altered.



To obtain the lines of the spectrum well developed, it is necessary to use a prism of very uniform substance, free from striæ, and having a refracting angle large enough to yield a very pure and extended spectrum. Prisms for the purpose are generally made of flint glass or rock-crystal, substances having a high dispersive power, that is to say, the power of refracting the red and violet rays in very different degrees (p. 623). A hollow prism filled with sulphide of carbon is also well adapted for the purpose, as it is sure to be uniform, if preserved from variations of temperature, and its dispersive power is very great. To form the spectrum, the sun's rays, or the diffused light of the sky, entering a darkened room through a narrow slit, or condensed by a cylindrical lens, are made to pass through the prism, and the dispersed beam of light is viewed through an achromatic telescope. The lines and intermediate spaces are thereby magnified, the number seen being greater in proportion to the magnifying power of the telescope. The most favourable position for the prism is that of minimum deviation.

Lines also exist beyond A in the red, and beyond the violet in a space occupied by very faint lavender-coloured rays. The first were observed by Brewster in a space

Digitized by Google

equal to AB (*fig.* 667), the second by Sir John Herschel. To render these lines visible, several precautions are required; amongst others it is necessary to intercept all the rays between the red and violet, and line the tube of the telescope with black velvet. By

Fig. 667.

adopting these and other precautions, and using a prism of oil of cassia, which possesses a high dispersive power, Brewster was able to distinguish altogether about 1000 lines in the spectrum, a map of which, together with a delineation of the two extremities of the solar spectrum, as observed by Gladstone when the sun was at about his greatest altitude, is given with a paper "On the Lines of the Solar Spectrum" by Brewster and Gladstone, published in the Philosophical Transactions for 1860, p. 149.

A still greater development of the spectrum, and an increased number of lines, are obtained by passing the rays through a series of prisms. In this manner Kirchoff has observed about 2000 lines, and has been enabled to lay down a very elaborate map of the solar spectrum, which is published in his work, translated by Roscoe, under the title—*Researches on the Solar Spectrum, and on the Spectra of the Chemical Elements.*

Gassiot has constructed a train of nine flint glass prisms with angles of 45°, and another of eleven sulphide-of-carbon prisms with angles of 45°, with which further observations have been made. (Proc. Roy. Soc. xii. 536; xiii. 183.)

Solar light reflected from a white surface, also that of the clouds, and that of the moon and planets, give spectra exhibiting the same principal lines, and disposed in the same order, as in the spectrum formed by the direct rays of the sun. In the spectra of Mars, Jupiter, and Venus, the lines D, E, F may be very clearly distinguished. But the fixed stars give spectra containing different lines. That of *Sirius* contains two dark lines in the blue, and one very strong line in the green, but none in the yellow or orange; that of *Pollux* contains several faint lines, the line D occupying apparently the same place as in the solar spectrum. See further a paper by Huggins and Miller. (Proc. Roy. Soc. xiii. 64.)

Effect of coloured Gases on the appearance of the Lines. When a ray of light passes through a coloured gas before falling on the prism, dark lines make their appearance due to the absorption of certain rays by the gas. When the light of a lamp, which of itself gives a spectrum containing only bright lines (p. 622), is passed through the red vapour of pernitric oxide, the violet and blue portions of the spectrum are covered with black lines or rather bands, which become broader as the density of the gas is increased, and ultimately join, so as completely to obliterate the violet rays; at the same time dark lines make their appearance in the yellow, and ultimately extend into the red (Brewster, Phil. Mag. [3], viii. 384). Iodine- and bromine-vapours produce dark lines different from those formed by pernitric oxide, appearing first in the green and yellow, then in the orange, and at the commencement of the red, some being quite black while others formed dark bands. The mere existence of colour in a vapour does not, however, necessitate the existence of bands in its spectrum. The red vapours of chloride of tungsten, for example, give no lines whatever. Neither can the position of the lines be inferred from the colour of the gas; with green perchloride of manganese, they are most abundant in the green, while with the red vapours of pernitric oxide, they increase in depth and number as they approach the violet. The vapours of simple bodies as well as of compounds may produce lines, and two simple bodies which singly do not produce them, may produce them abundantly in their compounds; *e.g.*, neither oxygen, nitrogen, nor chlorine, when uncombined, produces lines, but some of the oxides, both of nitrogen and chlorine, exhibit the phenomena in the most striking manner. There are, however, oxides both of nitrogen and chlorine, some of them coloured, which do not occasion the appearance of lines. Lines may also be produced by simple substances, which disappear in their compounds; thus iodine produces lines which do not appear in the spectrum of hydriodic acid. Sometimes the same lines are produced by different degrees of oxidation of the same substance, a remarkable instance of which is afforded by the oxides of chlorine. (W. A. Miller, *Elements of Chemistry*, 3rd ed. i. 164.)

When solar light is passed through a coloured vapour, the density of which is gradually increased, absorption-bands make their appearance, faint at first and easily distinguished, but gradually becoming blacker, and ultimately obliterating the ordinary lines. The two systems of lines are in fact distinct in the spectra of all coloured vapours, excepting that of pernitric oxide, in which they coincide. (Brewster.)

As the atmosphere possseses a slight colour, it is possible that some at least of the

Digitized by Google

ordinary lines of the solar spectrum may be due to the absorption o during their passage through the earth's atmosphere; and in fact the numerous, and some of them, especially those in the red, are remarkabl the sun is near the horizon, and its rays have consequently to travel thr thickness of atmospheric air, than when he is at a greater altitude; number of the lines are probably due to another cause, to be consid (Brewster and Gladstone, Phil. Trans. 1860, p. 149; Gladstone, xi. 305.)

Spectra of Flames and Incandescent bodies.

Incandescent solids and liquids give continuous spectra without an spaces. Flames, *i.e.*, incandescent gases or vapours, give spectra consi bands, more or less numerous, with dark spaces between. An alcohol of a Bunsen's burner in which common salt or other volatile sodiu ignited, gives a spectrum reduced to a narrow yellow band, coincident line D. Lithium ignited in a similar manner exhibits a single brigh near the solar C. The potassium-spectrum, similarly produced, consist coinciding with A, and a violet band not coinciding with any of the lines, the intermediate portion of the spectrum being filled up with a The thallium spectrum consists of an intense green line near the solar li split up by Gassiot's train of eleven sulphide-of-carbon prisms into three The spectra of the alkaline earths are equally definite, though mor (See Analysis, Inorganic; also Spectral Analysis.)

In some cases, new series of bands become visible as the temperature r spectrum of chloride of lithium in the flame of a Bunsen burner, giv intense crimson line; in a hotter flame, as that of hydrogen, it gives orange ray; and in the oxy-hydrogen jet and in the voltaic arc, a broad band likewise comes out. A similar effect is perceived in the case of m thallium, and other metals when heated by the voltaic arc. A. Mitsch Ann. cxvi. 499) has shown that in flames of low temperature, the lines with the compound employed, the spectrum then observed being that d pound, and not to its elementary constituents; the spectrum of copper differs considerably from that of an alcoholic solution of chloride of cop from an alcoholic solution of iodide of copper differs from both.

Spectra of the Electric Light.—The spectrum of the electric light e lines like those of flames. This was first observed by Wollaston, Fraunhofer, who found that the line of bluish light obtained by d electricity of a machine through a very fine wire, gave a spectrum con bright line in the green. Wheatstone has shown that the electric l voltaic battery, the ordinary electric machine, and the induction coil, y spectra when the spark passes between conductors of the same kind; b and position of the lines varies with the nature of the metallic poles; if t of an alloy, two systems of lines are obtained, one belonging to each the same is also the case when the two poles are formed of different m facts show plainly that the electric spark contains particles of metal deta conductors between which it passes.

Masson, in the course of his researches on electric photometry, already examined the spectra produced by various metals when employed as a Leyden jar, and when heated by the voltaic arc, and found them to c greater number of lines than those of the same metals delineated by W The difference was subsequently explained by Angström (Phil. Mag. who showed that Masson, in consequence of the intense heat of the elec which he employed, obtained two spectra, one due to the metal, the atmosphere itself, which became ignited. Certain lines observed by M mon to the spectra of all the metals, were really those atmospheric lines the spark to pass between the same metals immersed in various gases, lines due to the metal remained unaltered, whilst the others due t medium, disappeared and were replaced by new lines.

For further details, and for the methods of examining the spectra incandescent bodies, see Spectral Analysis.

Kirchhoff's theory of the Lines in the Solar Spectrum. The vapour of absorbs rays of the same degree of refrangibility as those which are e same substance in the state of incandescence, that is to say, those w bright lines of its spectrum. Thus ignited sodium emits a yellow light of which consists of two bright bands coincident with the double line spectrum. If now, through a flame coloured by sodium, the light of the oxy-hydrogen flame, or that of the voltaic arc between carbon-po

Sulphuric acid and oil of cassia, for example, produce spectra of nea
but in the oil of cassia spectrum, the least refrangible portion—namely
and yellow—is much less, and the more refrangible portion, from blue
more expanded than in that produced by sulphuric acid. In like m
contracts the less, and expands the more refrangible portion of the spec
extent than crown-glass. This irrationality of dispersion must of cou
in the formation of achromatic combinations.

The ratio of dispersion of two media is the ratio of the coefficie
$\frac{\mu_v - \mu_r}{\mu'_v - \mu'_r}$, or of the partial coefficients belonging to the corresponding
two spectra. This ratio has different values according to the two line
sidered.

The term dispersive power is applied to the ratio of the dispers
the index of refraction of the mean ray diminished by 1. Taking as
line E in the yellow, and calling its index of refraction μ_y, the dispers
pressed by the formula, $\frac{\mu_v - \mu_r}{\mu_y - 1}$.

The following table contains the refractive indices of several media
lines of the spectrum, as determined by Fraunhofer; the last column
efficients of dispersion between the lines B and H:

Cause of Dispersion.—As the several colours correspond to vibrations of different rapidity, and the deviation of rays of light in refraction depends on the change of velocity of light in passing from one medium into another, it follows that in order to explain dispersion, we must suppose that this change of velocity is different for rays of different colours, that is to say, that waves of different length travel through refracting media with different velocities. This consequence was for a long time regarded as a grave objection to the undulatory theory of light, being in fact in contradiction to the general formula for the velocity of undulations established by Newton, viz. $v' = \frac{e}{d}$. It must, however, be remembered that though the velocity of light in free space is the same for rays of all colours (p. 594), it is by no means necessarily so in transparent media, which retain the ether imprisoned, as it were, between their particles. The waves must then turn round these molecules, and it is easily conceivable that the retardations thus produced may be greater for the shorter than for the longer undulations. That such is the case has in fact been proved by the analytical researches of Cauchy; but the demonstration is not of a character to be introduced into this work, and does not admit of representation in a more elementary form.

Heating, Chemical, and Phosphorogenic Rays of the Spectrum.

All the rays of the solar spectrum are capable of giving heat as well as light. A thermometer held in any part of the spectrum indicates a rise of temperature; but the heating effect is very different in different parts, being greatest at the red end of the spectrum; but the particular position of the maximum heating effect varies with the kind of prism used. Moreover, there are invisible heat-rays situated beyond the red, and therefore of lower refrangibility than any of the luminous rays; and when a flint-glass prism is used, the maximum of heating power is situated beyond the visible red rays.

The spectra of flames exhibit similar results, provided the heat-rays which they emit are capable of passing through the substance of which the prism is formed, which is not always the case. (See RADIATION OF HEAT.)

The solar rays are also capable of producing chemical change, chiefly of the reducing order. Thus silver-salts are blackened and more or less reduced by exposure to daylight, and the leaves of plants, under the influence of sunlight, decompose the carbonic acid in the air, and assimilate its carbon. This action is exerted by all the luminous rays of the spectrum, but chiefly by the violet rays, and by non-luminous rays extending to a considerable distance beyond the violet. The yellow and red rays have but little chemical power: hence ordinary flames (hydrocarbon flames) in which these rays greatly predominate, exert but little action on chloride of silver and other bodies, which change rapidly under the influence of solar light; and in monochromatic yellow flames, such as that of alcohol containing a sodium-salt, the chemical action is altogether imperceptible. Photographers develope their pictures in rooms into which light is admitted only through yellow glass or yellow paper. Violet flames, on the other hand, like that of burning magnesium, emit rays whose chemical activity rivals that of sunlight, though their luminosity is incomparably less. The maximum of chemical action is not, however, produced upon all substances in the same part of

Digitized by Google

the spectrum. According to E. Becquerel (Ann. Ch. Phys
silver begins to blacken in the extreme violet between the
tion extending on the one side nearly to F, and on the othe
visible violet. With the iodide and bromide of silver, the
that the action does not extend so far beyond the violet,
not occupy the same place. Guaiac-resin, which is turn
sunlight, is not at all affected by any of the visible rays of
beginning only in the ultra-violet, and the maximum being s
the end of the visible spectrum.

The chemical spectrum contains fixed lines, that is to
chemical action is produced, so that when a piece of paper
silver or other sensitive substance has been exposed to the
surface is traversed by lines of the same colour as the origin

part of the spectrum. Moreover, Fizeau and Foucault have shown that the chemical actions produced at the focus of a lens by the light of the voltaic arc and the lime-light, are to one another in the same ratio as the luminous intensity.

The production of the several effects above mentioned by the same rays, is quite in accordance with the wave-theory of light. The waves of the ether striking on the surface of ponderable bodies throw their particles into vibration, and the particular effects produced are determined by the rate and mode of vibration thus excited, which themselves depend upon the manner in which the particles of the body are held together, as well as upon the rate of vibration of the incident waves. Rays whose length and rapidity of vibration are such as to excite in our organs the sensations of both heat and light, may, when they impinge upon a ponderable body, set its particles into such a rate of vibration as to excite in the surrounding ether, waves whose length and rapidity of vibration correspond to the least refrangible rays of the spectrum beyond the visible red. In like manner, we shall presently see that the invisible chemical rays at the other end of the spectrum may excite vibrations of less rapidity, which render visible the body on which they impinge. The effect thus produced is called

Fluorescence.

It was observed some years ago, by Sir John Herschel, that a solution of sulphate of quinine, though perfectly colourless by transmitted light, exhibits in certain aspects a peculiar blue colour. This blue light was found to be produced only by a very thin stratum of liquid adjacent to the surface by which the light entered, and the incident beam, after having passed through the stratum from which the blue light came, was not sensibly weakened or coloured, but had lost the power of producing the usual blue colour when admitted into another solution of sulphate of quinine. Light thus modified was said by Sir J. Herschel to be *epipolised*.

Similar phenomena were observed by Sir D. Brewster in an alcoholic solution of chlorophyll, the green colouring matter of leaves, the path of a beam of sunlight admitted into the green solution being marked by a bright light of a blood-red colour. The same appearance was afterwards observed in various vegetable solutions and essential oils, and in some solids. Brewster distinguished this phenomenon by the name of *internal dispersion*, attributing it to the irregular reflection of the light from coloured particles suspended in the liquid, and was of opinion that Herschel's epipolic dispersion was only a particular case of this internal dispersion.

The true explanation of these remarkable phenomena has, however, been given by Professor Stokes, who has shown that the peculiar dispersion produced by sulphate of quinine, and the other liquids above mentioned, is due *to a change of refrangibility in the rays of light*. The following experiment renders this evident:—

A solar spectrum is formed by means of an achromatic lens, and one or more prisms of flint glass, sufficiently pure to render visible the principal fixed lines, and a tube filled with a solution of sulphate of quinine is passed along this spectrum, from the red towards the violet end. Nothing peculiar is observed while the tube is held in the less refrangible part of the spectrum, the light passing through it freely and without sensible modification; but just before it reaches the extremity of the violet, a peculiar blue diffused light makes its appearance at the surface of the fluid by which the light enters, and remains visible, even after the tube has passed beyond the violet into the invisible portion of the spectrum, acquiring, in fact, its greatest intensity at a certain distance beyond the extreme violet.

The stratum of liquid from which the diffused blue light emanates is thinner in proportion as the incident rays are more refrangible; and, from a little beyond the extreme violet to the end of the spectrum, the blue space is reduced to an excessively thin stratum adjacent to the surface by which the rays enter. It appears, therefore, that the solution, though transparent with respect to nearly the whole of the visible rays, is of an inky blackness with respect to the invisible rays more refrangible than the violet. Nevertheless, these rays, when once they have been converted into the visible blue light, pass through the liquid with facility. They must, therefore, be essentially altered in character. Now, a change in the quality of light must consist, either in a modification of its state of polarisation, or in its period of undulation. The former supposition is excluded by the fact that the light thus modified is not polarised at all. It must, therefore, have undergone a change in its rate of vibration, and consequently a change of refrangibility. The existence of this change is, moreover, distinctly proved by examining the diffused light with a prism. It is then found to be by no means homogeneous, but to be resolvable into rays of unequal refrangibility, the whole of which are, however, comprised within the limits of the visible spectrum. *The diffused blue light consists of the chemical rays rendered visible by a change in their refrangibility.*

The diffusion thus produced is entirely distinct from that which is due to reflection

The colour and composition of fluorescent light sometimes afford valuable aid in distinguishing between one substance and another, and in testing the purity of solutions. With a solution of a *pure substance*, the tint of the fluorescent light is almost perfectly constant. But this tint, it must be remembered, is that of the light *as emitted*, not as *subsequently modified* by absorption on the part of the solution, in case the solution be sensibly coloured, and some precautions are required in order to observe it correctly. The fluorescence observed in solutions from the barks of the horse-chesnut, ash, &c., was formerly attributed indiscriminately to the presence of æsculin, whereas a purified solution from the bark of the horse-chesnut exhibits a fluorescence very sensibly different from that of æsculin, which observation alone would suffice to show that the bark must contain some other fluorescent substance besides æsculin.

The best mode of observing the true fluorescent tint is to dilute the liquid considerably, and to pass into it a beam of sunlight, condensed by a lens fixed in a board in such a manner that as small a thickness of the liquid as possible shall intervene between the fluorescent substance and the eye. If a stratum of this thickness of the dilute solution is sensibly colourless, the tint of the fluorescent light will not be sensibly modified by subsequent absorption. But as direct sunlight is not always to be had, the following method, requiring only diffused daylight, may also be used, the solutions being pretty strong, or at least not extremely dilute.

A glass containing water and blackened internally at the bottom is placed at a window, and the solution to be examined as to its fluorescent tint is placed in a test-tube which is held vertically in the water, the top slightly inclining from the window, and the observer regarding the fluorescent light from above, looking outside the test-tube. Since by far the greater part of the fluorescent light comes from a very thin stratum of liquid next the surface by which the light enters, the fluorescent rays have mostly to traverse only a very small thickness of the coloured liquid before reaching the eye; the water permits the escape of those fluorescent rays which would otherwise be internally reflected at the external surface of the test-tube, and the intensity of the light of which the tint is to be observed is increased by foreshortening. (Stokes, Chem. Soc. J. xi. 19.)

The nature of the solvent must also be attended to. The colour of the fluorescent light is liable to change, not merely in passing from an alkaline to a neutral or acid solution, but even occasionally in passing from one neutral solvent to another.

The composition of fluorescent light, as revealed by the prism, occasionally presents peculiarities, but in such cases they are found to be connected with peculiarities in the mode of absorption, so that the two are not to be regarded as *independent* characters of a substance; and as the peculiarities in the absorption are, as a general rule, the more easily observed, it is only rarely that the analysis of the fluorescent light is of much use.

The distribution of fluorescence in the spectrum often affords valuable information, but its observation requires the use of somewhat complicated apparatus. The observation is restricted to times when the sun is shining pretty steadily (unless the observer has recourse to electric light, or at least lime-light); it is requisite to reflect the sun's light horizontally, without which the observation would be most troublesome; and unless the reflexion be made by the mirror of a heliostat, the continual change in the direction of the reflected light is most inconvenient. It is requisite to use at least one good prism, better two or three, which must be of tolerable size, in order to have light of sufficient intensity, and the prisms must be combined with a lens, which need not however be achromatic.

It has already been stated, as the result of experience, that the colour of the fluorescent light of a single substance is constant throughout the spectrum, or very nearly so. If, therefore, on examining a solution in a pure spectrum thus formed by projection, we find the fluorescence taking a fresh start *with a different colour*, we may be almost certain that we have to do with a mixture of two different fluorescent substances, the presence of which is thus revealed without any chemical process. If, however, the fluorescence of two fluorescent substances, which may be mixed together, begins at nearly the same point in the spectrum (as commonly happens when there is merely a slight difference of tint in the colour of the fluorescent light of the two substances), the coexistence of the two may escape detection when the mixed solution is merely examined in a pure spectrum; and in such cases a combination of processes of fractional separation with the observation of the tint of the fluorescent light is more searching. This is the case, for instance, with the mixture of æsculin and fraxin contained in a solution from the bark of the horse-chesnut.

As the occurrence of a decided difference of colour in the fluorescent light seen at two different parts of the spectrum implies, almost to a certainty, the presence of two different fluorescent substances, so, conversely, the exhibition of the same colour is an argument in favour of the identity of the substance producing the fluorescence at the

exhibits, when examined by the hollow wedge and prism, a
very black lines; one in the yellow, the other in the green.
very weak solutions of didymium, and therefore serve as a de
they, moreover, afford means of distinguishing it from ceriu
spectra of which they do not occur.

Brewster's Theory of the Spectrum. Newton regarded the
an infinite number of simple colours, each element of it consi
refrangibility and not capable of further decomposition; and t
universally received as affording satisfactory explanations
colour, and of the decomposition and recomposition of ligh
studying the decomposition of light by absorption, observe
regarded as incompatible with Newton's theory, and he acc
theory of the constitution of the spectrum, which is as follow

1. White light is composed of *three* colours only, red, yel
certain proportions.

2. The solar spectrum is formed of three superposed spectr
them extending the entire length of the spectrum, but with va
in *fig.* 670; where the horizontal line *rv*, represents the length
three curves, R, Y, and B, are so drawn that their ordinate
intensities of the several colours at each point, the blue ha
the fixed lines F and G, the yellow near F, and the red, two
another of lower intensity near the
violet end of the spectrum.

3. All the colours of the spectrum are compound, and as all the rays united in one point have the same degree of refrangibility, they cannot be further decomposed by refraction.

Brewster was led to these conclusions by observing that when the spectrum is viewed through certain coloured media, white light may be s
of it. Thus, by looking through an azure-blue glass of suffi
through a solution of sulphate of copper mixed with red ink, th
replaced by white, very slightly tinged with green or red, ac
tint of the medium. This white light is not decomposible
decomposed by viewing it through a film of gelatin of ye
white band then appearing yellow or green, in consequence
blue or red rays. By similar means Brewster found white li
orange, whence he concluded that the three primary colours e
and orange of the spectrum. In like manner, by viewing the
yellow liquids, he found that the blue and indigo assumed

is *red*, it appears very bright in the red part of the spectrum, but th faint, the red surface reflecting the red rays of the spectrum abund colours in small proportions only. If the body is capable of abs completely, black bands are seen in the corresponding parts of the s body be illuminated solely by rays of that particular degree of refra black.

A coloured body illuminated by different sources of light m colours, the spectra formed by the light from these several sources the same colours or in the same proportions. It is thus that objects daylight appear blue by lamp-light, the yellow rays being less abu ordinary flames than in solar light. Most objects appear diff moonlight, from what they do by daylight. When a series of t colours of the spectrum is illuminated by the monochromatic ye fed with spirit containing common salt, the yellow, orange and red s of various degrees of brightness, the rest grey or black, because rays which they are capable of reflecting, or in other words, becaus not susceptible of vibrating in unison with those of the light whi In the same light, the face and lips appear of a livid hue, because the skin reflects in daylight are wanting in the yellow light.

When the body on which the light falls is transparent, the rays it are those which have not been reflected at its surface; henc transmitted light may be of different colours. Such is in fact th stances. Gold-leaf, which is yellow by reflected light, transmits ligh colour. Faraday formed pulverulent deposits by sending powerful through metallic wires in an atmosphere of hydrogen: in the finely produced, copper appeared green by transmitted light; tin, brow bluish-grey; palladium, brown; aluminium, brown or orange-colour and transmitted rays are sometimes complementary to each other; only when no part of the light is absorbed. When a body exhibi red for example, both by reflection and by transmission, it is bec of the red rays of the incident light, transmits the rest, and absorbs other colours.

In many cases, however, as pointed out by Professor Stokes (315), the colour of a body attributed on cursory examination to refl to transmission; in fact, the instances in which substances appear tion are comparatively rare. "A chemist views a solution containe transmission and then by reflection; and seeing perhaps some colour in the latter case, describes it as the colour of the solu whereas it is merely the colour by transmission due to a greater having been reflected at the back or bottom of the test-tube, an passed through the solution. In other cases, the colour described really arises from fluorescence; and though the statement may be intended, it seems objectionable to apply the term *reflection* to a different. It is only in the case of metals, such as gold and cop other substances, such as murexide, platinocyanide of magnesium, really seen as the result of reflection.

"When this takes place in the case of non-metallic substances, th endowed, for the colours so reflected, with an intense opacity, comp metals; while for other parts of the spectrum, they may be compara and these parts they reflect with an energy comparable to that of a only. The variations of absorbing power in passing from one part another, and consequently the variations in reflecting energy, are more considerable, and accordingly the colour by reflection is much case of metals."

"An excellent example of the intimate connection between met intense absorption is afforded by the crystals of permanganate of crystals exhibit a green metallic reflection, and when crushed yie intense purple colour by transmitted light. The colour is too i analysis, but the solution has a similar colour, merely less intense a its smaller concentration, and the analysis of the light transmitt presents no difficulty. The green is quickly absorbed, but when th ciently dilute, five eminently characteristic bands of absorption are of the spectrum. A sixth band comes out with a greater thickness solution, but even the fifth is somewhat less strong than the others. reflected from a crystal is analysed, four bright bands are seen stand rally luminous ground of inferior brightness. These bright bands tion with the principal *dark* bands in the light transmitted by

and those by which the light bands were produced in the num

1, 3, 5, 7, ... $2n+1$;

further, that the thickness of the film at the first bright band
inch for red light, and about $4\frac{1}{4}$-millionths for violet light.

Now comparing these numbers with those afterwards found b
of the waves (p. 600), it is found that the thickness of the film
length of a wave.

The explanation of this phenomenon is as follows:—The ban
terference of rays reflected from the upper and under surfaces
Now at the centre, where the two surfaces are in almost abs
expect the reflected rays to be in acordance—for they reach
over equal paths. At the first bright band, the thickness = $\frac{1}{4}$
the ray reflected from the second surface, which has to travers
behind the other by half an undulation, and might therefore be
other: but instead of that, the two assist each other and produ
larly with the other bright bands, which are produced by ray
length by

$\frac{3}{2}, \frac{5}{2}, \frac{7}{2}$ . . . . $\frac{2n+1}{2}$ of a wave-l

The dark bands are formed by rays which differ by

0, $\frac{2}{2}, \frac{4}{2}, \frac{6}{2}$ . . . . $\frac{2n}{2}$ of a wave-l

and which might therefore be expected to be in accordance.

The explanation of this apparent anomaly is found, as point
manner in which the direction of the vibrations of the ether-
passing from one medium to another.

When a wave of light travels through a medium of uniform
returns upon its path; no reflection takes place, but each part
state of vibration, communicates its vibration to the next, and
just as an ivory ball striking upon another of equal size, drive
is itself brought to rest. But if the vibration is communicat
ferent constitution—as when a ray passes from air into glass,
this complete destruction of the vibration of the particles does
consequence is, that the light is at the same time transmit
medium, and reflected back into the first. If the ray passes
the ether is of greater density to one in which it is of less
into air, the direction of vibration of the particles in the re
changed, just as a large billiard ball striking a small one, dri
it, and continues in its own course though with less velocity.
when the ray passes from air to glass, that is to say, from
ether of greater density, the vibration of the particles in t
versed—just as when a small ball strikes a large one, the larg
but the small one driven back upon its path.

To apply this to the case of Newton's rings. The bands a

This form of the diagram of colour, as perceived by the h
with Young's theory of *three primary sensations* of colour, w
proportions, when different kinds of light enter the eye. A
threefold character of colour, as perceived by us, is due, not
of light, but to the constitution of the visual apparatus, w
being affected in three different ways, the relative amoun
determined by the nature of the incident light. If we c
corresponding to the three primary sensations, each colour
of these sensations, then, since all other colours whatever
primary sensation, they must find their places in Newton's
of which the three primary colours form the angles.

If this theory be true, the complete diagram of all c
human eye, will have the form of a triangle. The colours c
rays of the spectrum must all lie within this triangle, and
mixtures of these, must lie within the line formed by the sp
colours correspond with the three primary sensations, they
of the triangle, and all the others will be within the triangl

The other colours of the spectrum, though excited by u
compound colours: because the light, though simple, has th
more colour-sensations in different proportions—as, for i
though not compounded of the blue rays and green rays,
pounded of those of blue and green.

The three colours found by experiment to form the three

There are but few substances capable of completely polarising generally speaking the polarising power is least in those media indices of refraction. According to Brewster, it is only those index is less than 1·7, which are capable of polarising complete marked with an asterisk in the preceding table. But even whe 1·7, the polarisation is never complete, if the beam of light is bri stances which reflect but little light, polarise a large proportio clean and polished surface, polarise scarcely at all. In all case law applies to the incidence at which the reflected beam contain of polarised light.

As the several coloured rays have different indices of refra only homogeneous light can be completely polarised by reflection nary gas or candle light, can never be made to disappear con above described. In fact, with media of high dispersive powe diamond, chromate of lead, or specular iron, all the colours of successively brought into view by slightly altering the inclin surface in the vicinity of the polarising angle. With glass a angles of polarisation for the extreme rays of the spectrum do n 15′ or 20′, the colours are less perceptible; nevertheless the l entirely, and always exhibits a slight coloration after the second

Light is more or less polarised by reflection at all angles o perpendicular incidence, the proportion of polarised light in th greater as the angle of incidence differs less from the polarisin Brewster's law.

If a ray, partially polarised by reflection at any angle differi angle, be again reflected from the same medium at the same a polarised light in it will be increased; and by a number of suc ray may be brought indefinitely near to the state of complete po of reflections required for the purpose being less as the angle o from the polarising angle.

2. *By ordinary Refraction.*—When light passes from one med fracted ray is polarised as well as the reflected ray, its plane perpendicular to the plane of refraction, or of incidence, and plane of polarisation of the reflected ray. The refracted ray wil from a surface of glass at an angle of 54½°, just under the circu ray polarised by reflection would not. Light, however, is neve by one refraction; but the proportion of polarised light in the re as the angle of incidence is nearer to the polarising angle; an tions through a number of surfaces of glass, or other mediu within any assigned limit of complete polarisation. A bundle or mica, bound together in a frame, forms a very convenient ap light, whether by refraction or by reflection.

3. *By Double Refraction.*—All crystalline bodies not belo system, possess the power of double refraction; that is t entering such a medium is split up into two rays of equal intensi crystal in different directions. In all such media, however, there directions in which double refraction does not take place, and the optic axes of the crystal. Transparent calcspar, or Iceland s in rhombohedrons, and exhibits double refraction more distinctl stance, is a crystal with one optic axis, the direction of that axis line joining the obtuse summits of the rhomb. A ray travers direction parallel to this axis is not divided into two; but in al ray is doubly refracted; and the two rays into which it is th completely polarised, the plane of polarisation of the one being pa *section* of the crystal, that is to say, a plane passing through t direction in which the ray traverses the crystal; the other in a to that section. The ray which is polarised in the principal sectio laws of refraction, remaining always in the plane of incidence, a cidences a constant index of refraction; but the ray polarised principal section follows different laws of refraction, its directio within the plane of incidence, unless that plane coincides with the principal section, and its index of refraction, excepting in th varying continually with the angle of incidence. The former o the *ordinary*, the latter the *extraordinary* ray. The mode of re will be more fully explained hereafter.

When these two oppositely polarised rays, which have traverse spar, fall on a plate of glass at the angle of 54½°, so placed that

Two such tourmalines mounted with their faces parallel to permit one of them to revolve in the plane of the axis, form a table apparatus for experiments on polarised light. A single convenient for examining light polarised by reflection or refr tion to the tourmaline is its colour, the best polarising tourm brown colour, which greatly modifies the colour of the transm in order that the tourmaline may polarise completely, it must least the tenth of an inch.

There are a few other double refracting crystals possessing particular the so-called "sulphate of iodo-quinine," discovered substance crystallises in thin six- or eight-sided plates, whi nearly colourless by transmitted light when viewed separately are superposed, with their longer dimensions crossing one ano part where they cross appears quite black, even if the thicknes exceed $\frac{1}{10}$ of a millimetre. The crystals of this compound n the same manner as tourmalines, and are even better adapted greater transparency and freedom from colour; but their fragi difficult to manipulate with them.

The best substitute for a tourmaline is the Nichol's prism, calcspar crystals being perfectly colourless and very transpare light than two superposed tourmalines.

All arrangements for examining the properties of polarised of two parts; viz., the **polariser**, by which the light is br state, and the **analyser**, by which its state of polarisation examined; thus, when a ray is reflected from a plate of glass the reflected beam examined by a tourmaline held before th is the polariser, and the tourmaline the analyser. It is cl apparatus above described, namely a reflector, a refractor, a d a tourmaline, or a Nichol's prism, may be used either as polar

Nature of Polarised Light.—The existence of rays ha on different sides was regarded by Newton as a decisive obje theory of light, on the ground that pressures or movements exc in an elastic medium ought to be equal in all directions; and to admit his inability to account for the existence of polarised theory as then understood. The reason of this apparent inab to explain the phenomena of polarisation, was that, at the tim ing, the vibratory movements of the ether were supposed to direction of propagation of the waves, and on that hypothesi ceive of rays of light, any more than rays of sound, possessin different sides. But later experimental researches, and the inv on the principles of analytical mechanics, have shown that th niferous ether take place in planes tangential to the wave-s the direction of the ray. From this point of view, the diffe and polarised light is easily explained. An ordinary or nat the vibrations take place in all directions successively in the p polarised ray is one in which the vibrations, still tangential confined to one plane. Suppose, for example, the direction of that of the wave-surface horizontal; then, if the ray be po vibration of all the particles will be either north and south, some one intermediate azimuth; and if it be unpolarised, place in all these directions successively.

This view of the nature of polarised light is established Fresnel and Arago on the interference of polarised rays, the g that *two rays whose planes of polarisation* (p. 653) *are paralle just like unpolarised rays: but two rays whose planes of polari to one another do not exhibit any phenomena of interferenc difference of phase.* These results are easily conceivable if the to the direction of the ray; for if the vibrations of the directions parallel to each other, the resultant will be equal of their individual movements, as explained at page 598, and that is to say, the rays will destroy each other, when their pha but if their vibrations are performed in planes inclined to c there will be, at every point, a finite resultant, determined in by the rule of the parallelogram of velocities, and never be Hence, two rays whose planes of polarisation are not parallel, to produce complete darkness; and if their planes are at righ they cannot interfere at all. If, on the other hand, the vibr

periment (p. 599), the rays are polarised by reflection in t of Young (p. 602), the rays originating from the same vibrations at each instant parallel to one another, so that n for interference.

s show then that the vibrations of the ether are parallel t in a polarised ray they take place, for the most part, in he ray. Moreover, *the vibratory movements are perpen- sation*. For when a beam of light passes through a crystal and spar, the *ordinary* ray is polarised in a plane parallel he crystal; that is to say, it is most easily reflected in a n (p. 653). Now as this ray follows the ordinary law of has a constant velocity whatever direction it may take rations of the ether which form it must have a constant axis of the crystal; and as they are perpendicular to the make with the axis, they could not form a constant angle were also perpendicular to that axis. The vibratory e ordinary ray are therefore perpendicular, both to the nd therefore to the principal section, which is the plane the axis, and in this case is identical with the plane of Hence, as all polarised rays possess the same properties, n, it follows that the vibrations of the ether are always at polarisation.

deduced from the properties of the tourmaline, which, as ntercepts the ordinary ray. Now it is found that a plate *ular to the optic axis*, intercepts all the light which falls idence, which shows that all vibrations perpendicular to

the straight line which is the direction of the ray, appea
arranged in the wave-line *acb*. If each of the vibrating partic
direction of its velocity will change from 0° to 180° while t
through the space of half an undulation, and to 360° in th
lation: hence, a series of particles in all phases of velocity
tremity of the wave to the other, will be situated on a screw-
of the ray for its axis. The ray is then circularly polari
according as the direction of revolution of the ether-molecu
centre of the circle, or the axis of the screw, is like that of th
contrary. The result is the same as if the ray were polaris
plane revolved, making a complete revolution during the time

If each of the vibrating particles describes an ellipse, the
be conceived as arranged on an elliptical screw-line. In th
state of polarisation of the ray, it is necessary to specify, no
major and minor axes of the ellipse, but likewise the position
determined, for example, by a system of rectangular co-ordi
with the ray, while the other two are drawn at right angl
plane of vibration of the ether-molecules. The direction of t
stated as in the case of circular polarisation.

A circularly polarised ray examined by an analyser ex
in all azimuths, just like natural light, but is distinguished
coloured when viewed through the analyser, after passing th
double refracting crystal (p. 671). An elliptically polari
mum and minimum of intensity in two positions of the analys
other, but is never completely extinguished like a plane-pola
coloured by transmission through a double-refracting film. T
both to circularly and to elliptically polarised light, differ fro
similar circumstances by plane-polarised light.

To understand the manner in which these different states o
necessary to take account of the movement impressed upon th

Moreover, as the variously directed vibrations of may be resolved into the two principal components above at the limiting angle, the vibrations of the ray (if mono- y all, be reduced to one plane—namely, a plane perpen- dence; in other words, the ray, after reflection, will be rly so, in the plane of incidence. The limiting angle the polarising angle (p. 653). It is clear also that if the a second mirror at the same angle, and this mirror is so f the polarised ray are parallel to its plane of incidence, lected from it; but that, if the second reflector be turned ays remaining at the same angle to the ray, the quantity

Digitized by Google

of light reflected will gradually increase till the plane of incidence
mirror coincides with that upon the first, at which the quantity of lig
the second mirror will be a maximum. (See page 653.)

When light falls at the polarising angle on a substance of cor
refracting power, as glass, water, &c., the intensity of the refracted ra
than that of the reflected ray, inasmuch as a small portion of the
right angles to the plane of incidence, and nearly the whole of that
parallel to the plane of incidence, pass into the refracted ray. The f
unites with an equal portion of the latter, reproducing unpolarised l
refracted ray consists of natural light mixed with light polarised
incidence.

The two components P and R not only differ in intensity after ref
wise exhibit a difference of phase, P being always more or less beh
according to Jamin, in reflection from one or two varieties of silica.

At the incidence of 90°, since a ray polarised in the azimuth
azimuth unaltered, the difference of phase of the two components
nothing or equal to an entire wave-length (p. 659). At perpendicul
azimuth changes from 45° to −45°; consequently the difference of pha
cases, therefore, a plane-polarised ray remains plane-polarised after
at all other incidences, the difference of phase is between λ and $\frac{\lambda}{2}$, and
plane or rectilinear polarisation is converted into elliptical polarisatio
incidence for which the difference of phase $= \frac{3\lambda}{4}$ is called the princi
It is very little smaller than the polarising angle (p. 653), calculate
formula, $\tan i = \mu$: hence, at the principal incidence, the quotient $\frac{P}{R}$
from its smallest value. In substances of small refracting power, the
difference of phase $\frac{\lambda}{2}$ to λ takes place quickly, so that the elliptical po
ceptible only between very narrow limits; but in bodies of greater

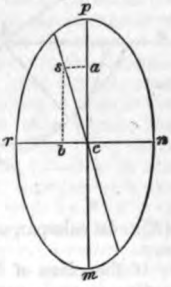
Theory of Double Refraction.



The phenomena of reflection, refraction, and coloration undergo co
tions when light falls upon media through which it travels with diffe
different directions. This is the case in all crystals not belonging
monometric system; likewise in all media whose molecular condition
ticular directions by pressure, or by heating and sudden cooling, such as

Crystals with one Optic Axis.—Consider, in the first place, crystals

given of double refraction in uniaxial crystals, it follows
l characterisation of such a body, it is sufficient to know
les of light therein, or—which comes to the same thing—
the two oppositely polarised rays which traverse the
lar to the axis. To find these indices of refraction, the
form of a prism, with its refracting angle parallel to the
ographic) axis, and the least deviations of the several
and extraordinary image measured by the methods already
found are, of course, true only for the particular tempera-
ired. Change of temperature likewise affects the refractive
rystals in a peculiar manner, because the rate of expansion
the direction of the optic axis, is not the same as in
hat axis. Calcspar, for example, expands in the direction
obtuse summits of the rhombohedron, more strongly than
ombohedron at the same time approaching in form to the
action perceptibly diminishes, or, in other words, the
E and *O* approach more nearly to equality. Very exact
refraction of Fraunhofer's seven lines (*B*—*H*), in the
images of calcspar and rock-crystal, together with the
by change of temperature, have been made by Rudberg
291). Double refraction is frequently also different in
oured rays. In apophyllite, indeed, this inequality is so
itively double-refracting for the blue, negatively for the
g for an intermediate ray.

To measure the angle between the axes, it is best to use h crystalline plate *c*, cut nearly at right angles to the median li in such a position that the plane of its axes may be vertical, round in its own plane, so as to bring each of the poles succ the intersection of the wires of the micrometer. The arc thr turned between the two positions gives the observed angle 2 optic axes (p. 664). From this the real angle between these a equation $\sin a' = \mu' \sin a$, in which μ' is the middle of the three indices for the coloured ray observed.

Soleil's apparatus serves also to measure the diameters of th being capable of turning round on itself, the diameters can ea required direction.

Double-refracting structure produced by Molecular Tensi other amorphous bodies, also crystals belonging to the reg double-refracting structure, when pressed, stretched, or heate parts, and exhibit, when examined by polarised light, colours produced by double-refracting crystals. A rectangular plate on a very hot iron plate, exhibits, when examined in a polarisi coloured bands parallel to its edges, these bands altering th heat is gradually conducted across the plate, and disappea becomes uniformly heated all over. A similar effect is produ in the same manner on a plate of metal cooled by a freezing m it to lateral compression.

These effects are, however, most strikingly exhibited by u to say, glass which has been heated and quickly cooled. G irregular structure, the parts near the surface having been m the interior parts, and torn away from them, as it were, by th cooling. In consequence of this irregularity of structure, th refraction on all rays which traverse it, but in different degr whence there results a variable coloration when the glass is vi The figures produced exhibit a symmetry depending on tha plate. A circular plate of unannealed glass, the structure o round the axis, acts like a uniaxial crystal, exhibiting concent a black or white cross, according to the relative positions of th If the structure is not quite symmetrical round the axis, the torted. A square plate exhibits a cross with coloured frin elliptical plate exhibits a figure resembling those of biaxial cr

Absorption of Light by Double-refracting Crys

Certain coloured double-refracting crystals, when traversed exhibit different colours according to the direction of the rays w thus dichroïte or iolite (ii. 320) appears of a yellowish white co or of a fine azure blue, according as the rays traverse it parall axis; in like manner, chloride of palladium and potassium exhi or a fine green colour; some varieties of sapphire are blue or green tourmalines appear dark brown-red when viewed along t

This effect is due to the property possessed by double-refract polarised rays in different proportions according to the inclin regard to their axes. The tourmaline absorbs completely all parallel to its axis, and transmits them in greater and greate is inclined to the plane of polarisation; moreover it absorbs posing white light in the same proportion, consequently the t always of the same colour, excepting in the case of the green tioned. But when the absorption-coefficients of the several ferent proportions with the change of direction of the rays formed by the mixture of the unabsorbed rays likewise varie to the axis.

Some biaxial crystals exhibit trichroïsm; thus certain B lowish rose tint in the direction of the median line, are violet complementary line, and yellowish white perpendicular to the

Babinet has observed that, of the two rays into which an i entering a uniaxial crystal, that which travels most slowly a fracted, is also absorbed in the largest proportion; in positive as tourmaline, it is the ordinary, and in negative crystals, like extraordinary ray which is most absorbed. This law, true in cases, nevertheless admits of numerous exceptions. Thus, Ha

Of the two acids thus obtained, the one which turns the plane of right is identical in every respect with ordinary tartaric acid; the ot tartaric acid. The two acids are also distinguished as dextro- an dextro- and lævo-tartaric acid. When equal weights of these two in water, and the solutions mixed, a liquid is obtained, which has on polarised light, and yields by evaporation, holohedral crystals of r similar result is obtained by mixing equal quantities of any of th acids, excepting the double salt of sodium and ammonium.

Hence it appears that racemic acid, a body which has no action up and crystallises in holohedral forms, is a compound of two acids (ta taric), which have equal and opposite effects on polarised light, similar but opposite hemihedral forms. These acids differ also in relations. The crystals of both become electric when heated, but extremities of the two exhibit opposite electrical states. Racemic electric.

Tartaric acid may be converted into racemic acid by the actio only it be associated with some substance which will enable it to bea temperature without decomposing. There are many substances polarised light is altered by heat. This is remarkably the case wi cinchona bark. When cinchonine, or any of its salts (which ro is heated in such a manner as not to produce decomposition, it is t isomeric alkaloïd, cinchonicine, which turns the plane of polar Similarly, quinine, which rotates the plane of polarisation to the l heat into quinicine, which turns it to the right. Now, when tar is heated, it is first converted into tartrate of cinchonicine, and if th tinued, the change extends to the tartaric acid, half of which is c tartaric acid. If the process be stopped at a certain point, and the with water, a solution is obtained which yields, first, crystals of anti wards, of tartrate of cinchonicine. But if the heat be longer contin unite, and form racemate of cinchonicine, from which racemic acid identical in every respect with ordinary racemic acid, and separable into the two opposite tartaric acids.

But, what is very remarkable, there is formed at the same time tartaric acid, which has no action whatever on polarised light, and y into the two opposite acids. In fact, when the fused mass obtained of cinchonine is treated with water, and chloride of calcium adde formed, consisting of racemate of calcium, and the filtrate, if left at re of the calcium-salt of inactive tartaric acid.

There are other organic compounds, which are also optically activ forms, but exhibit inactive and inseparable modifications. Malic in fruits, turns the plane of polarisation to the right; so likewise doe obtained by the action of acids and alkalis on asparagin. Now, bo be formed from fumaric acid, an optically inactive substance. Acid nium is $C^4H^3(NH^4)O^4 = C^4H^7NO^4$, which is also the formula of asp acid is actually formed by heating the acid fumarate of ammonium. acid thus produced is, like fumaric acid, optically inactive. Agai converted into malic acid by the action of nitrous acid:

$$C^4H^7NO^4 + HNO^2 = C^4H^6O^5 + N^2 + H^2O$$

Both active and inactive aspartic acids undergo this transfor aspartic acid yields active malic acid, and inactive aspartic acid yi acid. Neither inactive aspartic nor inactive malic acid can be separ oppositely active.

Common oil of turpentine possesses considerable dextro-ro the isomeric substance obtained by heating the artificial solid cam with quicklime is optically inactive.

Fusel oil has been shown by Pasteur to be a mixture of tw alcohol, which differ slightly in boiling point. One of these acids the other inactive.

Circular Polarisation induced by Magnetic action.—Faraday, in portant discovery, that bodies which, in their ordinary state, e action on polarised light, acquire the power of circular polarisation, the influence of powerful electric or magnetic forces. A polarised the axis of a prism or cylinder of a transparent substance, such as its plane of polarisation deflected to the right or left, as soon as jected to the action of an electric current passing round it at right or to that of two opposite magnetic poles (permanent or electro-m

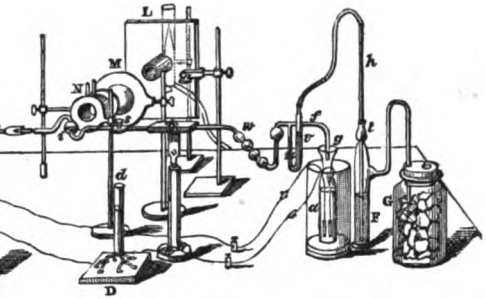
of the rotatory power by magnetic action: hence it is that developed in crystals. The development of this power is li sure, but favoured by heat, which increases the spaces bet thereby facilitates their displacement by magnetic action.

LIGHT, CHEMICAL ACTION OF. A large nun chemical change on exposure either to sunlight or to certain the action thus effected is said to be chemical action induced b or mechanical theory of light and heat easily explains this inasmuch as this theory supposes, in accordance with the prin of energy, that the rapid vibrations of the luminiferous ethe term light, are transferred to the smallest particles of the producing the chemical change. Amongst the most striking changes effected by the action of light may in the first place by light upon the salts of silver, giving rise to all the marvellou and secondly, the conversion of the carbonic acid gas contain stituent elements, by plants in sunlight, a chemical decomp whole living world depends.

The peculiar blackening which exposure to light effects up observed as early as the middle of the sixteenth century, bu phenomenon was first given by Scheele in the year 1777 (*Feuer*, Leipsic, 1784, p. 64). He clearly proved that when chl to light a black substance, insoluble in ammonia, but soluble i at the same time hydrochloric acid is set free; and hence Sch blackness which the *luna cornua* acquires from the sun's ligh Scheele likewise proved that the variously coloured solar rays in the same degree, and that the chloride of silver is blacke than in any other of the rays. The theory of the decomp light has made but slight progress since these first experimen the enormous development which practical photography has a present day, as regards the chemistry of the photographic pr advance far beyond Scheele's three fundamental discoveries, black powder insoluble in nitric acid, (2) the formation of (3) the specific activity of the violet rays.

The first definite experiments made on the chemical action were those of Priestley. This acute reasoner and active exper *ments and Observations on Different Kinds of Air*, Birminghs is only in presence of light that plants are able to decompose air, assimilating the carbon, and liberating the oxygen, and th mosphere rendered impure by the respiration of animals or by These results were soon afterwards confirmed and enlarged chemists and botanists, amongst others by Ingenhousz, D Ritter, and thus by degrees the grand relations of the atm animal and vegetable life became apparent. It is, however, years that the immediate dependence of all terrestrial life upo been universally admitted. We now know that the animal derives its power from the sun; that it is the rapidly vibrati absorbed by plants and stored up in them, to be given out aga energy, either animal or mechanical, upon the destruction o by oxidation. Only the most rapidly vibrating of the solar to effect chemical change, and hence these violet or most refra the special name of the "chemical rays;" there is, howev between these and the other solar radiations, they all differ onl intensity of vibration.

Measurement of the Chemical action of



The measurement of the chemical action of light and the which regulate these important actions are subjects which considerable attention. The first person who succeeded in roughly, the chemical action of light was Dr. Draper of New this purpose a reaction originally observed by Gay-Lussac an and hydrogen when mixed in equal volumes, do not combine exposed to diffused light, gradually unite, and even combine an explosion when placed in direct sunlight. Draper const which the quantity of hydrochloric acid formed by the action time could be approximately determined, and although the me was very incomplete, his experiments led him to the first gre

irect Sunlight.—The chemical action of the direct sun-
wing a small but known portion of direct sunlight to fall
the instrument was placed, so that the insolation vessel
rays thus admitted. By help of Silbermann's heliostat,
during the whole day upon one spot, a small opening of
hutter of a dark room. The fraction of the total sun's
wed to fall upon the chemical photometer was calculated,
was observed: hence the amount of action can be found
oduced if directly shining upon the instrument,—a con-
o fulfil, as the action would become too rapid and the
ttered by explosion.

tion of the sun's action must obviously be cloudless, if
the relation existing between the chemical action and the
g the observations as near sunrise as possible, we find, for
58, one of the days on which such a series of experiments
when the sun's zenith-distance was 76° 30′, the observed
at is, in one minute the column of water moved through
of hydrochloric acid formed, when the sun stood at the
ented by 1·52 division on the scale. Gradually, as the
ion for each minute became larger; until at $9^h\ 14^m$ a.m.,
on the day in question, owing to the formation of clouds,
ions, or was thirteen times as large as at $7^h\ 9^m$. In the
ying table is found the action, expressed in degrees of
observed at the foregoing times, if the whole sunlight had
strument:

Sun's zenith-distance.	Observed action. 1 minute.	Total sun's action in degrees of light.
76° 30′	1·52	5·54
73 49	4·22	15·50
71 37	6·09	22·43
68 34	7·56	27·85
67 30	8·38	38·87
64 42	12·48	45·85
60 48	17·09	62·59
58 11	18·51	67·61

chemical action with the rise of the sun in the heavens
that the solar rays, in passing through the air, are extin-
fact as light; and that as the sun rises higher above the
rough which the rays pass is constantly being lessened:
ect rays reach the earth.

which the direct rays of the sun are thus absorbed in the
experiments, of which the foregoing is only an example:
he sun produces, when at a given height, is known, it is
on which it would produce at any other height.

hemical action of direct sunlight may be thus expressed:
tion effected at a point upon the earth's surface on any
solar rays, depends alone upon the suns's zenith-distance,
lumn of air through which the rays have to pass.

ults agree very closely with the experimental data—with

the observed action—is seen by comparing the numbers in
observed and calculated action:

TABLE II.

Sun's zenith-distance at time of observation.	Chemical illumination of sun's rect rays at the earth's surface pressed in degrees of light.	
	Observed.	Calculated.
46° 8′	93·0	96·4
50 51	89·2	85·8
57 35	63·1	67·9
58 11	67·6	66·2
60 48	62·6	58·3
64 42	45·9	47·9
67 30	38·9	36·6
68 34	27·9	33·1
71 37	22·4	24·5
73 49	15·5	16·3
76 30	5·5	9·2
Probable error = ± 2·7 degrees of ligh		

Knowing the law which regulates the absorption of the
calculate what the action would be if there were no atmosphe
of the rays. It is thus found that if the sun's rays were no
sage through the atmosphere, they would produce an illumin
degrees of light; or they would effect a combination in one m
atmosphere of chlorine and hydrogen on which they fell per
of hydrochloric acid, 35·3 *metres in height.* The sun's rays h
larly through our atmosphere to the sea's level, effect an a
metres; or three-fifths of their chemical activity has been lo
persion in the atmosphere.

A large number of most interesting conclusions may be dra
noticed. Thus, for instance, we may determine the chemic
rays will produce on the various planets; for we know
chemical illumination varies inversely as the square of the di
the sun. The numbers in Table III. express this chemical a
and in heights of columns of hydrochloric acid called *light-me*
much the sun's chemical action varies on the different plan
receiving so small a portion as to render it impossible that
vegetable life which we here enjoy can there exist.

TABLE III.—*Chemical Action produced by Direct Sunli*

	Mean distances.	Ligh
Mercury	0·387	2
Venus	0·723	
Earth	1·000	
Mars	1·524	
Jupiter	5·203	
Saturn	9·539	
Uranus	19·183	
Neptune	30·040	

Interesting conclusions can be drawn from these facts, conc
the chemical rays on the surface of our earth in different
elevations above the sea's level. The farther removed a situ
the sea, the higher up in the atmosphere it is placed, the g
chemical action which it receives. Thus, in the highlands of
grain flourish at a height of from 12,000 to 14,000 feet, the ch
sunlight is 1½ times as great as in the neighbouring lowland
the same way we can calculate, for any point of the earth's
known, the amount of chemical action which the direct sun
time of day or year. In Table IV. the numbers represent the c
direct sunlight in one minute at the places and hours named, on

Optical and Chemical Extinction of the Chem
determine whether the act of photochemical combination (i
hydrogen) necessitates the production of a certain amoun
which an equivalent quantity of light is expended, or whet
pendent upon a restoration of equilibrium effected without a
loss of light, Bunsen and Roscoe have studied the phenomen
surfaces, and in the interior of a medium exposed to the che

When light passes through any medium, part of it is lost
another portion by absorption within the medium, so that
light is only a fraction of the incident light. This is t
with the luminous rays, and Bunsen and Roscoe have
of absorption and reflection of the chemical rays for gla
passing light from a constant source, through cylinders with
dry chlorine, they found that, with a given length of cylind
rays transmitted, when no chemical action takes place, is
dent light in a constant ratio; or in other words, the absorp
proportional to the intensity of the light. They also foun
chemical rays transmitted varies proportionally to the densi
If, however, the light passes through a medium in which it
also excites chemical action, it is found that, in addition to
ready spoken of, a quantity of light is lost proportional t
action produced. Thus the depth of pure chlorine gas at
through which the light of a coal-gas flame must pass in
is found to be 173·3 mm.: hence, since the quantity of lig
density, the depth of chlorine diluted with an equal volume
ing and chemically inactive gas required to produce an exti
mm. But when the sensitive mixture of equal volumes of
used, the depth of the mixture to which the light must pene
to $\frac{1}{10}$ is found only to be 234 mm. Hence Bunsen and Ro
in this case absorbed in doing chemical work.

Light from other sources gives results similar in chara
amount. Diffuse light of morning reflected from the zenith
to $\frac{1}{10}$ by passing through 45·6 mm. of chlorine, and through 73
ture; diffuse light is reduced to $\frac{1}{10}$ by passing through 19·7 m
57·4 mm. of the sensitive mixture. Hence it appears that
morning light are absorbed by chlorine much more quickly
and those of evening light with still greater facility. From
the chemical rays reflected at different times and hours, pos
but also qualitative differences, similar to the various colour
trum. Photographers are well aware of this qualitative diff
know that the amount of light photometrically estimated giv
chemical activity; they prefer a less intense morning light
for taking pictures.

Photographic Transparency, or Diactinic Power of differe
been mentioned (p. 632), that the chemical rays of the spectr
degrees by different media. On this subject, some important e
made by Professor W. A. Miller (Phil. Trans. 1863, p. 1
The mode of observation consisted in refracting the rays wh
parent medium, through a prism and lens of quartz, and r
of collodion coated with iodide of silver (p. 693), whereby
chemical spectrum was obtained. The light employed was
from an induction-coil between two metallic wires, general
peculiarly rich in chemical rays, yielding a chemical spect
times the length of the visible spectrum. The following are
results obtained:

1. Colourless solids which are equally transparent to the
in permeability to the chemical rays.—2. Bodies which are
rent in the solid form, preserve their transparency in the li

Photography.

The first well-authenticated attempts to produce pictur
action of sun-light were made by Thomas Wedgwo
the year 1802;† but it would appear probable from recen
ton and Watt actually obtained sun-pictures at the S
year 1799. No written statement of the method employ
however, as yet been found, and we must therefore still giv
the credit of having first described a mode of obtaining p
light. The method adopted by Wedgwood was that of
leather with a solution of nitrate of silver. By this means h
on glass, and took profiles, and Davy even succeeded in
seen in the solar microscope; but neither of these chem
unshaded portions of the picture from being coloured by e
the year 1814 M. Niépce examined the action of light o
with the object of obtaining an unalterable image in the c
to a certain extent, inasmuch as the light rendered the res
vents, so that, by the subsequent action of an acid on the
parts upon which the light had not fallen were etched. In 1
an account of his experiments to the Royal Society, and i
M. Daguerre, who had been previously but unsuccessfully
of the particulars of his process. The two investigators
common, proposing many different modes of producing the
they were termed, without great success, until the death o
continuing his experiments after this event with the s
enough to discover, in 1839, the method which bears his
and pension offered by the French government for the dis
manently fixing the image formed in the camera. The p
essentially in allowing the vapour of iodine to act upon a p
thus becomes coated with a thin film of iodide of silver; t

Nature of the Chemical Change effected by Light on Silver Salts.—Although the exac chemical decomposition effected by light on the chloride, bromide, and iodide of silve has long been a subject of experimental discussion, still much remains to be learn concerning the composition of the photographic image. The general result of investig tions upon this subject may be stated to be that, in the first place, a sub-salt of silve of a grey or violet colour is formed, whilst by a further action of the light the silver i probably reduced to the metallic state. It appears, however,* most difficult to prepar the sub-salts of silver in a pure state, either by the action of light, or by other chemic methods, the evidence of the presence of such a salt in the violet-coloured chlorid depending upon the well-known fact that this substance is unacted upon by nitri acid, but decomposed by ammonia into chloride and metal. The recent experiments o Vogel (Pogg. Ann. cxvi. 497) confirm this result, as he shows that when pure and dr chloride and bromide of silver are insolated, chlorine and bromine are liberated, an a substance insoluble in nitric acid, in each case, produced: he was unable to dete free iodine when pure iodide of silver is exposed to light, and hence he concludes th this salt is not decomposed by light. Vogel has likewise observed that the result obtained when the above-mentioned salts are prepared with an excess of silver-sal instead of an excess of the precipitant, are somewhat different: thus, whilst the iodid prepared with excess of iodide of potassium shows no change of colour, that prepare with excess of silver becomes decidedly grey on exposure to light.

A singular effect produced by the red rays upon a blackened silvered paper wa observed long ago by Ritter, and confirmed by Herschel. If prepared paper soaked i nitrate of silver solution be blackened by exposure to light, and then submitted to th action of the solar spectrum, those portions upon which the violet rays fall becom darker, whilst those exposed to the red rays become lighter, and assume a brick-re colour; hence it would appear that the least refrangible rays exert opposite action upon the sensitive silver-salts. Claudet has also shown (Phil. Trans. 1847) that ex posure to the red rays neutralises the effect previously produced on a sensitise daguerreotype plate by white light.

We are as yet quite unacquainted with the essential nature of the change brough about by the action of light. Thus, we do not know whether, in the blackening c chloride of silver, the light used up in the decomposition is equivalent to the wor done, as in the case of the decomposition of water by the galvanic current where th force needed to separate the molecules of oxygen and hydrogen is as large as tha evolved by the combinations of the gases; or, whether the chemical actions of light re semble that sudden splitting up which occurs in certain compounds (the chlorid of nitrogen, for example) where they are placed in circumstances under which the can no longer exist, and where the force establishing the change bears no equivalent rela tion to the forces developed in the resulting decomposition.

Chromo-photography.—Many attempts have been made to reproduce in the photo graph the colours of natural bodies; and although these attempts have not succeede to the full extent of fixing the coloured picture, yet a certain degree of progress in th production of tinted images has been made. Thus, for instance, Becquerel (Ann Ch. Phys. [3] xlii. 81) has described a method by which a coloured image of the sola spectrum can be prepared, as well as representations of the coloured rings formed i crystals by polarised light. In order to obtain these coloured images, a polished plat of silver is immersed in dilute hydrochloric acid, and a film of sub-chloride forme upon the silver by allowing the plate to form the positive electrode of a Bunsen's bat tery The plate thus prepared becomes variously tinted when exposed to the sola spectrum, some of the rays being reproduced with their distinctive colours, whils others either produce no effect or give rise to tints differing from their own. Othe experimenters, especially Niépce de St. Victor and Campbell, have obtaine somewhat analogous results; but, as yet, the coloured images produced by these an similar processes have resisted all attempts to render them permanent.

Photographic Engraving, Lithography, and Galvanography.—Th original photographic process proposed in 1827 by Niépce has been lately modifie by M. Niépce de St. Victor, for the production of photographic engraving on steel A plate of steel is covered with a layer of prepared bitumen, and being placed under an ordinary positive photograph, is exposed to light; on treating the bitumen with naphtha and benzol, those portions which have not been insolated dissolve, leaving the steel plate exposed for the subsequent action of acid. The plate thus prepared is then sub mitted to the usual processes employed in aqua-tint engraving. A somewhat similar process was patented by Mr. Fox Talbot, in 1858, for etching by chemical means a positive photograph on a copper plate. This method has recently been modified

LIMACIN. A substance obtained by Braconnot (Ann. Ch. P
from the garden-snail (*Limax agrestis*). When dry it forms a white ea
crumbled between the fingers. It is somewhat soluble in cold, more s
water, soluble in boiling alcohol, in concentrated hydrochloric acid, an
line liquors. The solution in cold water is precipitated by tannic acid
limate, neutral lead-acetate, ferrous sulphate, and the acetates of copper
but not by oxalate of ammonium. By dry distillation it yields carb
nium, and leaves charcoal with a small quantity of alkaline ash.

LIMAX. According to A. Vogel and C. Reischauer (N. Jahrb.
many coloured snails of the genus *Limax* contain a colouring matter
violet in dilute acid solution, brown or black in more concentrated
obtained by macerating the animals, freed from their viscera, with di
and precipitating the solution with ammonia. The brown or black iri
tate is insoluble in water and in alcohol. The nitric acid solution gra
a crimson colour, then becomes colourless. The colouring matter, when
a large quantity of phosphate of calcium.

LIMBERLITE. Syn. with Chrysolite (i. 958).

LIME. Oxide of calcium (see Calcium, i. 718).

(iii. 237).

LIME, OIL OF. $C^{10}H^{16}$.—The volatile oil of *Citrus Limetta*, obt
ling the torn and pressed rinds with water (i. 1003).

LIME-FLOWER, OIL OF. A volatile oil, obtained from the
europæa, by distillation with water (Brossat, J. Pharm. vi. 396), or
with ether in a percolator. The amount does not exceed 0·1 per cent.
than water, very volatile, and has a strong odour of lime-flowers. (G

LIMESTONE. The generic name of all rocks having carbonate
their principal constituent. The principal accessory constituents are
1. Silica and alumina. The former occurs in crystalline limestones,
crystalline quartz; in compact limestones, sometimes as sand in small
frequently combined with alumina, in the form of clay. Nearly all lim
small quantities of clay, and in some the quantity amounts to several
the limestone then passing into marl. Limestones also occur contai
calcium, as at Gjellebäk in South Norway.—2. Iron: sometimes as ferr
times as ferrous carbonate; generally only in small quantities and trace
nese: either as manganic oxide or as manganous carbonate. In still s
than the iron, and often absent altogether.—4. Magnesia, as carbonate:
accessory constituent of limestones, but in true limestones not exceed
per cent. When the proportion is larger, the limestone passes into d
stone and dolomite.—5. Phosphoric acid: appears to occur only occas
very inconsiderable quantity, no limestone having yet been found to
than 0·2 per cent. of it.—6. Alkalis, namely potash and soda, have be
considerable number of limestones by Schramm (J. pr. Chem. x
Fehling (*ibid.* 446). Schramm found from 0·1 to 0·3 per cent. alkali
part as carbonate, in smaller quantity as chloride. Fehling obtained f
limestones about 3 per cent. alkaline carbonate. According to Schram
occurs in larger quantity than potash, about in the ratio of 2 at. soda to
7. Organic (bituminous) matter, probably in all limestones, excepting
line ones; sometimes in mere traces, sometimes in more considerable q
anthraconite, stinkstone, and bituminous limestone, the presence of or
very conspicuous.

The following enumeration of the sub-species and varieties of lime

Ann. Ch. Phys. [2] xiii. 338.)

It contains margarin (palmitin, according to Schüler; stearin
Unverdorben), and a glyceride of linoleic acid (Sacc). By saponifi
$\frac{1}{10}$th margarate, and $\frac{9}{10}$ths linoleate of lead (Gusserow, Kastn. Arch.

Linseed oil exposed to sunshine for some weeks, in contact with an
of an equal weight of protosulphate of iron, becomes limpid and colou
to the air in thin layers, it dries up to a transparent, resinous, moderat
resembling caoutchouc; when heated, however, it does not melt, bu
burns (Leucho, Kastn. Arch. iii. 107). A peculiar fat is produced a
together with a crumbly substance, insoluble in ether (Hoppe, J.
117). Mixed with chalk so as to form a powder, and exposed to
weeks, it dries up completely, and on dissolving out the carbonate
hydrochloric acid and exhausting the residue with ether, a whi
consistence of tar is obtained, which behaves like oleic acid altered by
air. There remains behind resinous linseed oil in the form of a yell
rate mass, which is insoluble in alcohol, ether, volatile and fixed oils,
alcoholic hydrochloric acid into a tarry substance, and dissolves in
(Unverdorben, Schw. J. xvii. 245).

Impure oil, containing mucus or albumin, becomes rancid in the a
in sunshine, and has then a repulsive odour and taste, a dark
reaction. Concerning the formation of ozonised oxygen in the oxidati
see Schönbein (J. pr. Chem. lxxiv. 338). When the oil is boiled
till it loses about $\frac{1}{8}$ of its weight, it becomes thicker, tenacious,
dries up still more readily than in the fresh state to a tough, turpe
scarcely soluble in oils: *Printers' varnish.* (See Ink, p. 272.)

Linseed oil (also nut or poppy oil), heated to about 323°—
and burns quietly, without further heating from without, till tar or c

fatty substance having the odour of butyric acid (Sacc).—With *sili* oil does not form elaidic acid. (Pelouze and Boudet.)

In contact with aqueous *ammonia* and alcohol, it is attacked wi yields a small quantity of warty crystals of an amide which melts at 97°, and dissolves easily in alcohol; it contains, on an average, 75·25 H, and 5·03 N, and has therefore the composition of margaramide, identical. (Rowney, J. pr. Chem. lxvii. 159.)

Linseed oil yields, with *alkalis*, a very soft soap. On heating wit of caustic soda of specific gravity 1·34, it turns yellow and remains By distillation with an excess of alkali, it evolves hydrogen, together v and yields a green distillate. (Al. Müller, *Handwörterb.*, vi. 874.)

Potassium and *sodium* oxidise in linseed oil somewhat more quickl oils, with formation of soap. (Gay-Lussac and Thénard.)

Linseed oil is oxidised with peculiar facility by *acid chromate* dilute sulphuric acid, and yields an acid, strongly-smelling distillate Ann. Ch. Pharm. lxxiii. 199.)

It dissolves oxide of lead when heated, and is decolorised thereby a easily drying, forming what is called *boiled oil* (see Liebig, Ann. C 110; W. Henry, Scher. J. ii. 636; Schindler, N. Br. Arch. xli. 146 *Handwörterb.* iii. 123). When shaken with *basic acetate of lead* a throws down a turbid mucus containing oxide of lead, above which nish containing 4 or 5 per cent. oxide of lead. Exposed to the su *mercuric oxide*, it reduces the mercury to a liquid mass (Fuchs, xx. 200); partial reduction takes place in strong sunshine, the oxide b grey; but it is only when heat is applied, that a small quantity of (Ann. Ch. Pharm. xx. 200.)

Linseed oil dissolves, according to Bucholz, in about 5 pts. of bo of cold alcohol; according to Brandes (Gilb. Ann. xliv. 289), in specific gravity 0·82 and in 1·6 pt. ether.

LIPARITE. Syn. with FLUOR SPAR (ii. 677).

LIPIC ACID. $C^5H^8O^5 = C^5H^6O^4 . H^2O$ according to Lau Phys. lxvi. 169); $C^5H^8O^4$ according to Wirz (Ann. Ch. Pharm. cv formula places it among the homologues of oxalic acid, included in th $C^nH^{2n-2}O^4$. This acid, discovered by Laurent, is produced, together beric, adipic, and other acids, by the action of nitric acid upon oleic, s acid, and is contained in the mother-liquor which remains after the p acids have been separated.

The best mode of preparing it, is to heat oleic acid in a retort fo with an equal weight of nitric acid of ordinary strength, then add fre repeat the operation four or five times. The united solutions are the to a fourth of their bulk, and the concentrated liquid left at rest, t beric acids crystallise out. The remainder of the nitric acid must the the mother-liquor by evaporation as completely as possible, taking c does not blacken from too great concentration; the crystals which consisting of adipic and lipic acids, are dried and dissolved in hot et a few brown impurities undissolved; the solution is left to evaporat and the liquid which covers the crystals is evaporated. The two prod by evaporating the ether are separately dissolved in boiling alcohol, are left to evaporate in the air. By repeating these operations severa are obtained, viz. adipic acid crystallised in rounded tuberculous a and lipic acid in slightly elongated laminæ (Laurent), in translucen of nodular groups of small prisms. (Wirz.)

Lipic acid is moderately soluble in cold *water*. When a few grain on a watch-glass, till partial fusion takes place, the acid crystallise fibrous mass, while a portion volatilises and condenses on the no beautiful needles having the form of prisms with rectangular base.

The acid crystallised from water, contains 1 at. water, which it los the anhydrous acid then condensing in long shining needles (Wirz very suffocating and excites coughing. When deprived of its water it does not melt below 140° or 145° (Laurent); according to Wirz It is very soluble in *alcohol* and *ether*.

Lipic acid is dibasic, the formula of its s lts being $C^5H^6M^2O^4$, whi that of the itaconates (Laurent); $C^5H^6M^2O^4$ (Wirz). The salts sulphuric acid give off lipic acid.

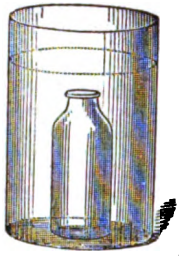
ost transparent. It was formerly sold under the name of
., iv. 386.)

ON OF. When two liquids of different density, and
in contact, diffusion takes place between them, much in the
ses, excepting that, as the particles of the liquid are less
he gas, the rate of diffusion is slower. The phenomena of
nutely investigated by Graham, in two classical series of
Philosophical Transactions for 1850 and 1862, also in the
iety, iii. 60, 257; iv. 83, and xv. 216; and important con-
ave also been made by Fick, Simmler and Wilde,



s with the nature of the liquids, the temperature, and in
ie degree of concentration.
Solutions. The apparatus used in Graham's first series
a set of phials of nearly equal capacity, cast in the same
by grinding to a uniform size of aperture. The phials
a neck 0·5 inch in depth, and aperture 1·25 inch wide;
l to 2080 grains of water or between 4 and 5 ounces. For
glass water-jar was also provided 4 inches in diameter and

fluid" as synonymous with liquid; but this is incorrect; *fluid* is, pro-
solid, and includes both liquid and gas.

Digitized by Google

The diffusion-phial was filled with the saline solution, sal-ammoniac the base of the neck, or more correctly to a distance of 0·5 inch f surface of the lip. The neck of the phial was the

Fig. 708.

distilled water, a light float being first placed on the solution, and care being taken to avoid ag the phial had been placed within the jar, water the jar, so as to cover the open phial to the de which required about 20 ounces of water. The the phial is thus allowed to communicate freely in the jar. The diffusion is interrupted by placi of ground glass on the mouth of the phial, and ra out of the jar. The amount of salt diffused, cal sion-product, or diffusate, is ascertained by water in the jar to dryness, or, in the case of ch cipitating with nitrate of silver.

The results of several series of experiments made are given in the following table, the second column the quantity of salt in 100 pts. of the solution, one per cent. of sal 20·8 grains; the third, the time of diffusion; the fourth, the temp Fahrenheit scale; the fifth, the quantity of salt diffused in grains:—

These experiments, and a number of others made in a similar manner, lead to the following general conclusions:

1. Different salts, in solutions of equal strength, diffuse unequally in equal times.

2. With each salt, the rate of diffusion increases with the temperature, and at any given temperature, is proportionate to the strength of the solution, at least when the quantity of salt dissolved does not exceed 4 or 5 per cent.

Later experiments (Chem. Soc. J. xv. 235) have shown that diffusion increases at a higher, though not greatly higher, rate than the temperature, and that the more

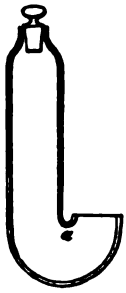
nowever, is true only with regard to cylindrical columns of liquid, or the horizontal section is of uniform magnitude. In other cases, the l density may be calculated according to the form of the vertical sec shaped tubes Fick has shown that the results of calculation agr experiment.

Now let K denote the quantity of salt which, in the normal s passes, in a unit of time, through a unit of horizontal section of a whose height is equal to the unit of length; this quantity is call *coefficient;* also, let Q be the quantity of salt which, in the time mouth of the tube into the water-atmosphere; h, the height of horizontal section; and d, the density of the liquid at the bottom; t



$$Q = K . d . \frac{h}{s} t.$$

Hence, with a tube of given dimensions, and a solution of kno density at the bottom, the *diffusion-coefficient* K, of any salt may be the quantity Q, diffused out in a given time.

This method has been applied by Fick only in the case of chlorid is, in fact, though simple in principle, somewhat inconvenient of appli of the long time—at least fourteen days—which must elapse before th attained.

Another method of determining the diffusion-coefficient of a salt has Jolly, and applied in several cases by Beilstein (Ann. Ch. Pharm.

Beilstein infers from his experiments, that the rate of diffusion proportional to the difference of density of two contiguous strata, b somewhat greater ratio.

Simmler and Wilde (Pogg. Ann. c. 217) are of opinion that th ment of Beilstein's results with this law arises from a defect in experimenting. Beilstein's calculations, indeed, are based on the sup strength of the solution in the tube (*fig.* 709), though constantl uniform at any instant of time throughout the entire length; wher sideration will show that the density near the orifice must be less t larger arm of the tube, and in this arm less than near the bottom of the liquid must stagnate to a certain extent. From this source of er of observation is free. Simmler and Wilde, however, propose other of execution than Fick's, and not subject to the necessity of waiting state of diffusion is established. One of these methods is similar by Graham (p. 706), excepting that the vessel containing the solut cylindrical, a condition which greatly simplifies the calculations; and, placed at the bottom of the water-jar, is supported on a stand, so as to within a line or two below the surface of the water; the salt, as it dif made to flow over the sides of the vessel and fall to the bottom, leavin of pure water above. the chloride of sodium is found to have diffused in sensible quantity
could have risen higher. The top of the diffusion-column of sulphate
and likewise that of sugar, appear to have just reached the top of t
fourteen days of the experiment. But the colloïds, gum, tannin, albumi
exhibit a great falling off in the rate of diffusion. Gum and tannin d
be carried by diffusion higher than the seventh stratum, the minute quan
the higher strata, which together do not exceed 0·02 grm., being doub
of accidental dispersion, arising probably from a movement of the upp
sioned by slight inequalities of temperature. The diffusion of albumin
is still slower.

By continuing the diffusion of different substances till equal quantiti
out, the following results were obtained:

Approximate times of Equal Diffusion.

Hydrochloric acid	1
Chloride of sodium	2·33
Sugar	7
Sulphate of magnesium . . .	7
Albumin	49
Caramel	98

The diffusion of hydrochloric acid in three days corresponds with t
chloride of sodium in seven days. Hydrochloric and the allied hydrac
monobasic acids, are the most diffusive substances known.

The diffusion process in alcohol appears to be several times slower
The following table exhibits the results of experiments on three subst
in alcohol, and placed under a column of alcohol, the experiments be
exactly as described at p. 700.

Separation of Arsenious Acid from Colloïdal Liquids.—Dialysis m
ously applied to the separation of arsenious acid and metallic s
solutions in medico-legal enquiries. The process has the advantage
metallic substance or chemical reagent of any kind into the org
arrangement for operating is also of the simplest nature.

The organic liquid is placed, to the depth of half an inch, on a dia
hoop of gutta percha 10 or 12 inches in diameter, covered with parchme
p. 716). The dialyser is then floated in a basin containing a volum
four times greater than the volume of organic fluid in the dialyser.
basin is generally found to remain colourless after the lapse of 24
being concentrated by evaporation, it admits of the application of th
to precipitate and remove a metal from solution. One-half to thr
crystalloïdal and diffusible constituents of the organic liquid will gene
the water of the basin.

Tartar-emetic and strychnine may be separated from visci
in a similar manner: indeed, all soluble poisonous substances appear
and therefore pass through colloïdal septa.

LIQUIDS, DISPERSIVE POWERS OF. See LIGHT (p. 62

LIQUIDS, EXPANSION OF. See HEAT (p. 52).

LIQUIDS, INDICES OF REFRACTION OF. See LIGHT

LIQUIDS, OSMOSE OF. When two liquids are separated
tion of a porous diaphragm, a flow of liquid takes place from one si
to the other, or sometimes an unequal flow of the two liquids in op
so that the quantity of liquid increases on one side of the septum a
the other. This phenomenon was originally designated by the corre
dosmose and Exosmose, but it is better expressed by the shorter
from ὠσμός, impulsion), which includes the two former.

The passage of liquids through porous septa was first studied by Du
apparatus, called an *endosmometer*, consisted of a narrow glass tube,
shaped expansion at the bottom, and closed at that end by a piece o
tube was filled with a saline solution, and placed in a vertical position
ing water. The flow of liquid in the one direction or the other was
rise or fall of the liquid in the tube. Dutrochet inferred, from his expe
velocity of the osmotic current is proportionate to the quantity of s
substance originally contained in the saline solution. The experimen
inexact, because no allowance was made for the alteration of hyd
caused by the rise or fall of the liquid in the tube. Vierordt (Pogg.

the liquids.

Osmose in membrane presents many poi
to that in earthenware. The membrane is co
ing decomposition, and its osmotic action is ex
and other substances capable of determining a
all chemically active substances, while the great
organic substances and perfectly neutral monob
metals, such as chloride of sodium, possess o
of action, or are wholly inert. The active su
most efficient in small proportions.* With a
ing $\frac{1}{10}$ per cent. of carbonate of potash, the rise
was 167 millimetres; and with 1 per cent. of th
millimetres in five hours. With another
stronger solution, the rise was 863 millimetres,
inches in the same time. To induce osmose, th
on the membrane must be different on the
apparently not in degree only, but in kind,
action on the albuminous substance of the
one side and an acid action on the other. T
always to accumulate on the alkaline or basic
brane. Hence with an alkaline salt, such as carbonate of sodium, i
and water outside, the flow is inwards; but with an acid in the os
negative osmose, or the flow is outwards, the liquid then falling in
chlorides of barium, sodium, and magnesium, and similar neutral salts,
ferent, or appear to act merely in a subordinate manner to some ot
basic substance, which may be present in the solution or the membr
minute quantity. Salts which admit of division into a basic salt and
an osmotic activity of the highest order, *e.g.* the acetate and vario
alumina, ferric oxide and chromic oxide, cuprous chloride, stannous
of lead, &c. The acid travels outwards by diffusion, superinducing
of the inner surface of the membrane, and an acid condition of the
most favourable condition for a high positive osmose. Again, the
potassium and sodium, such as the sulphate and tartrate, though s
properties, begin to exhibit a positive osmose, in consequence, perhap
tion into an acid supersalt and free alkaline base.

The following table exhibits the osmose of substances of all class
brane, the degree being a rise or fall of 1 millimetre:—

* The action increases with the strength of the solution up to a certain point, as
show. With stronger solutions the pores of the membrane probably becomes tou
of salt, and the action consequently diminishes.

The degree of hydration of any gelatinous body is much affecte medium in which it is placed. This is very obvious in fibrin and an Placed in pure water, such colloïds are hydrated to a higher degree t neutral saline solutions. Hence the equilibrium of hydration is diffe sides of the membrane of an osmometer. The outer surface of the me contact with pure water, tends to hydrate itself in a higher degree surface does, the latter surface being supposed to be in contact with a When the full hydration of the outer surface extends through the membrane and reaches the inner surface, it there receives a check. The tion is lowered, and water must be given up by the inner layer of the it forms the osmose. The contact of the saline fluid is thus attended catalysis of the gelatinous hydrate, by which it is resolved into a lowe drate and free water. The inner surface of the membrane of the osm by contact with the saline solution, while the outer surface dilates by c water. Far from promoting this separation of water, the diffusion of t out the substance of the membrane appears to impede osmose, by equ dition as to saline matter of the membrane through its whole thickne tage which colloïdal solutions have in inducing osmose, appears to depe the low diffusibility of such solutions, and their want of power t colloïdal septum.

The substances fibrin, albumin, and animal membrane swell greatly in water containing minute proportions of acid or of alkali, as is well k other hand, when the proportion of acid or alkali is carried beyond a p each substance, contraction of the colloïd takes place. Such colloïd named, acquire the power of combining with an increased proportion forming superior gelatinous hydrates, in consequence of contact with alkaline reagents. Even parchment-paper is more elongated in an a than in pure water. When so hydrated and dilated, the colloïds pre osmotic sensibility. Used as septa, they appear to assume or resign gelatination under influences apparently the most feeble. It is not atte this varying hydration of colloïds with the osmotic effects thence phenomena belong to colloïdal chemistry, where the prevailing changes appear to be of the kind vaguely described as catalytic. To the futu of catalytic affinity, therefore, must we look for the further elucida (Graham, Chem. Soc. J. xv. 268.)

LIQUIDS, TRANSPIRATION OF. (Poiseuille, Ann. C 50; xxi. 76; Jahresber. 1847–8, p. 139; Graham, Phil. Trans. 1861, Soc. J. xv. 427.)—This term is applied to the passage of liquids th tubes under pressure, in accordance with the analogy of gaseous transpi The first experiments on the subject were made by Poiseuille, who manner in which the flow of the liquid is related to the pressure, an and diameter of the tubes; also, in many cases, the manner in which the nature of the liquid. Graham's enquiries were directed chiefly between the rate of transpiration and the chemical composition of the l

densation of the mixed liquids occurs,—which degree of dilution corr
hydrate, $C^2H^6O.3H^2O$, has been made by Graham the starting-point
series of experiments on the relation between capillary transpiratio
composition. The 3-atom hydrate of methylic alcohol, $CH^4O.3$
distinguished by any particular degree of condensation in volume, exhi
in its transpiration rate, similar to that of dilute ethylic alcohol. The h
also, in many cases, exhibit a characteristic retardation of transpiratio
degree of hydration. In hydrated substances generally, the extent to
tion is affected by annexation of water, is by no means in proportion t
combination. In sulphuric acid, for instance, the maximum t
occurs with the hydrate $H^2SO^4.H^2O$; in acetic acid, with the compou
of nitric acid with $2HNO^3.3H^2O$; and with alcohol, as above ol
hydrate $C^2H^6O.3H^2O$. The transpiration-times of these hydrates ar
other results, in the following table, in which the transpiration-time
same temperature is taken as the unit of comparison:

Transpiration-times of Acids, Alcohols, and Ethers. (Gra

Liquid (undiluted).		Transpiration-time.	Degree hydrati
Water		1·0000	
Methylic alcohol	CH^4O	0·6300	+ 3H
Ethylic alcohol	C^2H^6O	1·1950	+ 3H
Amylic alcohol	$C^5H^{12}O$	3·6490	
Formate of ethyl	$C^3H^6O^2$	0·5110	
Acetate of ethyl	$C^4H^8O^2$	0·5530	
Butyrate of ethyl	$C^6H^{12}O^2$	0·7500	
Valerate of ethyl	$C^7H^{14}O^2$	0·8270	
Acetic acid	$C^2H^4O^2$	1·2801	+ H
Butyric acid	$C^4H^8O^2$	1·5650	+ H
Valerianic acid	$C^5H^{10}O^2$	2·1550	+ H
Nitric acid	NHO^3	0·9899	+ $\frac{2}{3}$H
Sulphuric acid	SH^2O^4	21·6514	+ H
Acetone	C^3H^6O	0·4010	+ 6H

On comparing the transpiration-times of the several alcohols, eth
this table, it will be seen that, so far as these observations extend, th
sion of individual substances in any homologous series is indicated b
transpirability as clearly as by their comparative volatility, the h
having the slowest rate of efflux. It may also be observed that the t
of an acid is slower than that of an ether with which it is metameric;
example, is slower than acetate of ethyl.

LIQUORICE. See Glycyrrhizin (ii. 920).

LIRIODENDRIN. A neutral substance, existing, according
stem of the tulip-tree (*Liriodendron tulipifera*). It is obtained b
bark with water, concentrating to one-fifth, washing the impure
separates with weak potash, and crystallising from boiling dilute
tallises in scales or in radiating needles. It is bitter, melts at 83°,
sparingly soluble in water, very soluble in alcohol and ether. It i
strong hydrochloric or sulphuric acid, the latter converting it int
Iodine colours it yellow.

LIROCONITE. *Octahedral Arsenate of Copper, Chalcophac*
This mineral occurs in trimetric crystals, exhibiting the combination
sionally an inch in diameter, but usually minute. Angle ∞P :
$P\infty$: $P\infty = 72° 22'$. Cleavage lateral, but obtained with difficulty.
Hardness = 2 to 2·5. Specific gravity = 2·882 to 2·985. Lustre vitr
resinous. Colour and streak sky-blue. Fracture imperfectly con
Imperfectly sectile.

When heated it turns green and begins to glow, then becoming d
charcoal before the blow-pipe it melts slowly, and forms a red bri
reduced with carbonate of sodium, it yields white scales of ars
(Damour). It is completely dissolved by acids, and even by ammon

n. with Heavy Spar.

ight 7, *Symbol*, Li.—Lithia, the oxide of this metal, was
1817. It was first obtained from petalite (silicate of alu-
nich it exists to the amount of 5 per cent.; it exists also
ent.), amblygonite (11 per cent.), triphyline (3·4 per cent.),
pyrite, and the tourmaline of Uton in Sweden. The most
yet discovered is a mineral spring in Cornwall, analysed by
the British Association, 1864). In smaller quantities it is
found in sea-water, in many micas and felspars, in the ash
in sea-water, and in many mineral springs.—Bunsen has
eorite of Juvenas in France, and in that of Parnallee in
. Pharm. cxx. 253), and Engelbach has found it in the
gg. Ann. cxvi. 512.)
nalen, viii. 120) stated that a white combustible metal is
e action of the electric current, but metallic lithium was
m by Bunsen (Pogg. Ann. xciv. 107). The process is as

is fused over a spirit-lamp in a small porcelain crucible,
arbon battery of 4 to 6 cells. The positive pole is a small
rd carbon deposited in gas-retorts), and the negative pole
kness of a knitting-needle. After a few seconds, a small
ed under the fused chloride, round the iron wire and
vo or three minutes attains the size of a small pea. To
ole and regulus are lifted out of the fused mass, by a small,
ila. The wire may then be withdrawn from the still melted
m oxidation by a coating of chloride of lithium. The metal

The *hydrated chloride*, LiCl.H²O according to Rammelsberg, LiCl. to Hermann and Troost, is formed when the anhydrous chloride deliqu or when the aqueous solution is evaporated at a rather low temperatu and crystallises in large rectangular prisms with four-sided summit lateral edges: it is probably isomorphous with hydrated chloride of sod crystallisation, it forms needles grouped in feathery tufts like (Hermann). Both the anhydrous and the hydrated chloride deliquesc air, and dissolve very readily in water and in alcohol. (C. Gmelin.)

LITHIUM, DETECTION AND ESTIMATION OF. 1. *the dry way.*—Lithium salts are white, excepting those which contain such as chromic acid. They are more readily fusible than the corres potassium and sodium, and are permanent in the fire, if the acid is no easily decomposed. Fused with *carbonate of sodium* on platinum a dark yellow stain round the circumference, whilst carbonate of sodiu luces this effect to a much smaller degree only (Berzelius). Fus wire they colour the blowpipe flame carmine-red. An excess of a pota not interfere with the production of this colour, but the presence of a of soda gives rise to the yellow flame (H. Rose). Alcohol, in which a is dissolved or diffused in the state of fine powder, also burns with flame (C. Gmelin). The same occurs also with paper saturated of a salt of lithium, or the wick of a taper saturated with moistened ph tate of lithium (Turner, Ed. Phil. J. of Sc. ii. 267; iv. 113). By spectroscope, the occurrence of very minute traces of lithium may be brilliant crimson band, having a refrangibility between those of the lines solar spectrum, and a faint yellow band somewhat less refrangible than these two lines the whole light of the lithium spectrum is contained, w the gas-flame of a Bunsen's burner. At very high temperatures, howev of a hydrogen-flame, a blue line also makes its appearance.

2. *Reactions in Solution.*—All salts of lithium are soluble in carbonate and phosphate, and the double phosphate of lithium and s slightly soluble. Hence the other salts of lithium, when not dissolve water, yield difficultly soluble precipitates with *carbonate of ammonium sodium*, and with *phosphate of sodium*. *Carbonate of sodium* precipita lithium after some time only. Common *disodic phosphate* does not prec the cold, even after a long time, except on the addition of ammonia, w gives rise to an abundant precipitate. But a mixture of a salt of lithi phate of sodium becomes turbid by boiling or evaporation, and the being treated with water, leaves the difficultly soluble phosphate of lithi

Phosphate of potassium gives no precipitate, even on boiling or evapo the addition of *ammonia*, an abundant precipitate after some time (H. *drofluosilicic acid* throws down from salts of lithium the almost insol silicium and lithium (Berzelius), and *picric acid* precipitates picrate Rose). Solutions of lithium-salts, even when concentrated, are not perchloric acid, sulphate of aluminium, dichloride of platinum, oxalic a acid.

A solution of a salt, which is not clouded by caustic soda in the col nate of sodium at a boiling heat, but yields with phosphate of sodium, an almost insoluble white powder, contains lithia. (Berzelius.)

3. *Quantitative Estimation and Separation.*—Lithium, after s other metals, may be estimated as carbonate, sulphate, or chloride. The h organic salts of lithium are converted into carbonate, Li^2CO^3, when ign with the air. All lithium-salts containing volatile acids, may be conv phate by heating them with sulphuric acid: the excess of acid may simple ignition, without addition of carbonate of ammonia, because lit form an acid sulphate. The chloride is not so well adapted for quantitat as the sulphate, on account of its hygroscopic qualities; but as lithiu obtained as chloride, in the process of separating it from sodium, it is estimate it directly in this form: it must be ignited in a well-covered weighed immediately after cooling.

Lithium may also be estimated as phosphate, Li^3PO^4, by evaporating a lithium-salt with phosphate of sodium, adding a quantity of hydrate sodium sufficient to keep the liquid alkaline; digesting the residue and washing the precipitate with a mixture of equal volumes of water then drying at 100°, and igniting. The determination may be render by repeatedly evaporating the filtrate and wash-water, and treating the s of lithium-phosphate thereby separated, as before (W. Mayer, Ann xcviii. 193; Jahresb. 1856, p. 739). According to Rammelsberg (

Digitized by Google

olutions of lithium treated with phosphate and carbonate
rm M^3PO^4, containing variable quantities of lithium and
itschr. Annal. Chem. i. 42) finds that the precipitate ob-
he composition Li^3PO^4, and, accordingly, that Mayer's
correct results.

the earth-metals and heavy metals in the same
namely, by sulphydric acid, sulphide of ammonium, or
From potassium it may be separated by *dichloride of*
otassium, but not lithium; and from sodium, by con-
chlorides, and treating the dried chlorides, in a well
of *ether* and *absolute alcohol*, which, in the course of a
e of lithium, and leaves the chloride of sodium.

ss is somewhat tedious, and is apt to be rendered inexact
Bunsen (Ann. Ch. Pharm. cxxii. 348) recommends the
stimating lithium, when it exists in the state of mixture
ali-metals. The anhydrous mixture of the chlorides of
y exhausted with ether-alcohol; the residue obtained by
gain treated in the same manner; and the evaporated
ted and weighed. It is then dissolved in water; the
letermined by precipitation with nitrate of silver; the
ss of silver by hydrochloric acid, and the potassium con-
chloride of platinum. The quantity of chloride of potas-
hen deducted from the total weight of the chlorides, a
lithium + y chloride of sodium; and the quantity of
the known quantity of chloride of potassium, gives, when
of the chloride of silver, a weight B, whence the quan-
alculated by the formula—

$$x = 1{\cdot}0823\ B - 2{\cdot}6525\ A.$$

thium. The earlier determinations of this number by
Gmelin, and Kralovansky, were much too high, having
containing sodium. Hermann, Berzelius, and Hagen,
n free from sodium by precipitation with carbonate of
inte sulphate, which was then analysed by precipitation
Berzelius obtained the number 6·5. The numbers ob-
n were lower, and even that of Berzelius has been shown
o be too low, the error probably arising from partial
e of lithium during fusion.
. 349), by decomposing chloride of lithium with nitrate
s 6·92 and 6·96. Diehl (Ann. Ch. Pharm. cxxi. 93),
of lithium, the purity of which had been tested by
omic weight of the metal = 7·026. Troost (*ibid.* cxxiii.
carbonate with silicic acid, obtained the number 7·01;
ave the same result; and the decomposition of the car-
ded the number 7·06. From all these results, the num-
omic weight of lithium.

E OF. This compound crystallises from the aqueous
e grains, which, at the temperature of commencing red-
ain becoming cloudy as it solidifies. It is very slightly
s.)

F. *Lithia*, Li^2O.—*Anhydrous lithia* is obtained as a
containing a certain quantity of peroxide, by burning
the product to cool in a stream of the gas. (Troost,

ined from petalite, spodumene, or lepidolite, which are
ost advantageously from lepidolite), or from triphyline,
um, manganese, iron and aluminium, by the following

thia-spodumene, reduced to fine powder by careful levi-
s weight of quicklime; the mass is treated with hydro-
ric acid; the resulting sulphate of lithium is dissolved
um; and the last traces of calcium are removed by pre-
mmonium. The solution of sulphate of lithium is then
aryta-water just sufficient to throw down the sulphuric
ration yields hydrate of lithium.
. [3] li. 121) heats 10 pts. of finely-powdered lepidolite

with 10 pts. of carbonate of barium, 5 pts. sulphate of barium, and 3 potassium. The fused mass separates on cooling into a heavy transp supernatant white crystalline slag, consisting of the sulphates of potassium, and sodium, and containing nearly all the lithium. The are dissolved out by water, and converted into chlorides by chlorid potassium is precipitated by chloride of platinum, and the chlorid sodium are separated by means of alcohol and ether. In operating the double sulphate of lithium and potassium may be separated l tallisation.

3. Triphyline is dissolved in strong hydrochloric acid, nitric ac bring the iron to the state of ferric oxide; the solution is evaporate the residue is treated with water, which leaves all the iron as ins The solution containing the chlorides of lithium and manganese phoric acid, is treated with sulphide of barium, which removes t stances; the excess of barium is removed by sulphuric acid (or bette ammonium), and the filtrate is evaporated to dryness and ignited. C thus obtained frequently contains chloride of sodium, which may alcohol and ether. The chloride is then converted into sulphate, a caustic lithia is obtained as above. (Müller, Ann. Ch. Phys. [3] xl

Hydrate of Lithium, LiHO, separates from the aqueous solution i grains. It has the same taste, causticity, and alkaline action on veg potash and soda, but is much less soluble in water. It melts eas forming a fused mass which has a crystalline fracture. It does not a at a white heat.

Fused lithia, as commonly prepared, corrodes platinum vessels p silver vessels should always be used for heating it. This action upo indeed, to be one of the best indications of the presence of lithium; Troost (Ann. Ch. Pharm. cxxiii. 384), it is not produced by pure pure lithium-salt, but only by such as contain cæsium and rubidium

Peroxide of Lithium is said by Troost to be formed, together lithium is burned in oxygen gas.

LITHIUM, SULPHIDE OF. Li^2S. This compound is for is thrown on melted sulphur; also when sulphate of lithium is heat charcoal. It dissolves in water and alcohol more easily than lithia.

LITHOGRAPHY. See PRINTING, CHEMICAL.

LITHOMARGE. *Stone-marrow* (*Steinmark*). A kind of cla are two varieties, the friable and the indurated.

Friable Lithomarge.—Colour white. Massive and sometimes in scaly and feebly glimmering; streak shining. Slightly cohering Feels rather greasy; adheres to the tongue. Light. Phosphoresces constituents are, according to Klaproth, silica 32, alumina 26·5, ir sodium 1·5, and water 17·0. It occurs sometimes in tin-stone veins

Indurated Lithomarge. Colours yellowish and reddish-white. M daloïdal. Dull, opaque. Fracture fine earthy. Streak shiny. easily frangible; adheres strongly to the tongue; greasy to the touch 2·44. Infusible before the blowpipe. Some varieties phosphoresce, moistened, afford an agreeable smell like that of nuts. Its cons 45·25, alumina 36·5, oxide of iron 2·75, water 14, and a trace of pot It occurs in veins in porphyry, gneiss, &c., at Rochlitz in Saxon (Jameson.)

LITHOSPERMUM. The root-bark of *Lithospermum arven* colouring matter, which reacts with water, alcohol, ether, and alkali as that of alkanet (i. 128), excepting that the lithosperm-red form with ether, whereas alkanet-red forms a dark red solution. (Ludwig Rép. Chim. app. 1859, p. 211.)

LITMUS. *Lackmus. Tournesol en pains.*—A blue colouring m for preparing test-papers. It is obtained from various species of *Ro* and *Lecanora*, the same lichens in fact that yield archil (i. 355). I experiments of Gélis (Revue Scient. vi. 50) that the blue co developed in the lichens by fermentation, when the proximate prin them are metamorphosed in presence of an alkaline carbonate. Un the air and ammonia alone, these lichens yield nothing but archil; carbonate is likewise present, the lichens undergo a totally different product of the fermentation, instead of being red or violet, has then This blue coloration is due to the combination of the new colourin

o remove the ether, leaves Erythrolein in the form of a
portion of the alcoholic extract which is insoluble in ether
.

which remains after the boiling with alcohol (*vid. sup.*)
in. This substance is either boiled with pure water, and
evaporating the strongly coloured solution; — or the
l is boiled with ammoniacal water, and the blue solu-
luring which operation the greater part of the ammonia
parated by moistening the mass with hydrochloric acid, and
monia with alcohol.

iquid obtained by boiling litmus with water is precipitated
l; the precipitate washed with water, treated while still
and suspended in warm ammoniacal water; the dark blue
yness, and moistened with hydrochloric acid; and the
y means of warm alcohol. The residue is but of small
the deep colour of the solution; it sometimes consists
rarely of Spaniolitmin, a substance not containing

amorphous powder which dissolves with blue colour in
d violet lakes.

n obtained mixed with azolitmin, but it appears to be of a

l mass of a fine red colour, and dissolves in ammonia,

talline grains of a fine deep red colour, coloured blue
h ammonia, a blue compound insoluble in water.

nalytical results obtained by Kane with these substances,
atomic weight of carbon (6·12 or 12·24):

rolein.	Erythrolimin.		Azolitmin.		Spaniolitmin.
4·27	55·78	55·3	49·50	50·05	44·54
0·68	8·69	8·1	5·35	5·52	3·11

zolitmin is the only one which contains nitrogen. Kane
ly by the comparative method which gave proportions of
3 to 1 : 18·3.

tmin approaches pretty nearly to the formula $C^7H^7NO^4$
nitrogen 8·2), according to which azolitmin would contain
n, and might be derived from orcin in the manner shown by

$$C^7H^8O^4 + NH^3 + O^3 = C^7H^7NO^4 + H^2O.$$

of the alkaline carbonates in the formation of litmus may
hat these salts accelerate the absorption of oxygen by orcin
f air and ammonia, so as to produce a new compound more
ïn.

Digitized by Google

The ammoniacal solution of azolitmin forms with the salts of the he tates which are red or blue, according to the quantity of metal contai azolitmates of *barium* and *calcium* are blue. The *lead-compound* violet colour when recently prepared, but becomes blue when drie to contain $2C^7H^6PbNO^4.Pb^2O$. The *stannous salt* is a lake of a fi exposure to the air in the moist state it is converted into a *stan* splendid scarlet colour.

Azolitmin suspended in water through which chlorine gas is p chlorazolitmin.

Azolitmin subjected to the action of nascent hydrogen, is disso into a compound called by Kane, leucazolitmin, which, however pure, because it oxidises immediately and becomes coloured when A white compound of leucazolitmin with stannic oxide is form stannous compound of azolitmin with water; on exposure to the ai converted into the scarlet stannic compound of azolitmin.

LIVER, GLYCOGENIC FUNCTION OF. See Glycog

LIVER OF SULPHUR. An old term applied to a mix sulphides of potassium, obtained by heating sulphur with carbonat covered vessel. (See Potassium, Sulphides of.)

LIXIVIATION. The application of water to the fixed resid purpose of extracting the saline part.

LIXIVIUM. A solution obtained by lixiviation.

LOADSTONE. Magnetic iron ore (p. 397): see also Magn

LOAM. See Clay (i. 1023).

LOBELINE. An alkaloïd existing, according to Bastick and J. Trans. x. 270, 456) in *Lobelia inflata*. It is oily; cannot be decomposition; dissolves very readily in water, alcohol, and ether lisable salts with hydrochloric, sulphuric, nitric, and oxalic acids. precipitated by tannin. It acts as a narcotic when taken internally

LOBOITE. A magnesian vesuvian from Norway. (See Vesuv

LOELINGITE. Syn. with Leucopyrite (p. 585).

LOEWITE. A sulphate of magnesium and sodium, Mg^7Na^2 Ischl, approaching astrachanite in composition. It is of yellow gravity 2·376, and gives by analysis 52·35 SO^3, 12·78 MgO, 18·2 and 0·66 Fe^2O^3 and Al^2O^3 = 99·21. (Karafiat, Haid. Ber. 1846,

LOGANITE. A variety of pyrosclerite from Calumet Isla Canada, where it occurs associated with serpentine, phlogopite, p in crystalline limestone. It has a weak subresinous lustre, pale colour, and greyish streak. Hardness = 3. Specific gravity = 2·6 in crystals with rounded angles, which appear to be pseudomor angle 124°, near that of hornblende. Contains 32·49 per cent. sil 35·77 magnesia, 0·95 lime, 2·14 protoxide of iron, and 16·92 water acid) = 101·45. (T. S. Hunt, Phil. Mag. [4] ii. 65.)

LOGWOOD. *Bois de Campèche. Blauhols.*—The tree whic is called by Linnæus, *Hæmatoxylum campechianum*.

Logwood is so heavy as to sink in water, hard, compact, of a fin being polished, and scarcely susceptible of decay. Its predominant with orange, yellow, and black.

It yields its colour both to spirituous and watery solvents. Alcoh readily and copiously than water. The colour of its dye is a fine r to violet or purple, which is principally observable in its watery de to itself, becomes in time yellowish, and at length black. Acids tur deepen its colour, and give it a purple or violet hue.

Stuffs would take only a slight and fading colour from decoction were not previously prepared with alum and tartar. A little alum bath. By these means they acquire a pretty good violet.

A blue colour may be obtained from logwood, by mixing verdigri dipping the cloth till it has acquired the proper shade.

The great consumption of logwood is for blacks, to which it give very cast, and for greys of certain shades. It is also of very extensi compound colours, which it would be difficult to obtain of equal be means of drugs affording a more permanent dye.

part of the retort begins to be covered with radiant masses of lophin tion of secondary products ceases, nothing being formed but lophine a At the commencement, a small quantity of an aromatic oil accomp apparently resulting from the decomposition of the amarine into l products, the principal of which is amarone (Gössmann and Atk cation as in Laurent's method (1).

Properties.—Lophine forms colourless needles, often an inch long, and having a lustre similar to that of caffeine; they become opales but retain their lustre. At 250° the compound sublimes, gradually without previous fusion, and without decomposition. It melts at transparent liquid, which at 260° solidifies in a radiating crystalline less and inodorous, with scarcely any alkaline reaction. The alcoholic fluorescence like quinine, but not in so high a degree. It has no act light (Gössmann and Atkinson). G. Kühn (Chem. Centr. 1 tained, by the dry distillation of hydrochlorate of hydrobenzamid modifications of lophine, one crystallising in needles which melted (likewise obtained by Ekman, Ann. Ch. Pharm. cxii. 151) in need at 170°.

The composition of lophine has been variously represented by the and $C^{28}H^{16}N^2$ (Laurent), $C^{21}H^{16}N^2$ (Fownes), $C^{21}H^{17}N^2$ (Gössma son), $C^{28}H^{16}N^2$ (Lisst). Fownes's formula, $C^{21}H^{16}N^2$, agrees best, o the analyses, and likewise affords the best representation of the form pound from hydrobenzamide (or from amarine):

	Calculation.		Laurent.		Fownes.	Gössman
C^{21}	252	85·1	85·6	86·0	85·2	85·7
H^{16}	16	5·4	5·4	5·1	5·4	5·5
N^2	28	9·5	9·2	· ·	9·1	· ·
$C^{21}H^{16}N^2$	296	100·0	100·2		99·7	

Laurent's second analysis, which differs considerably from all the made with impure material.

Lophine is insoluble in *water*, very sparingly soluble in boiling crystallising in needles on cooling. It dissolves to about the same a and in *oil of turpentine*, whence it separates in a crystalline powd dissolves easily and without decomposition in boiling *alcoholic potash*.

According to Ekman (Ann. Ch. Pharm. cxii. 151), 100 pts. of a 19° dissolve 0·81 pt. of lophine, and at 21° from 0·84 to 0·91 pt. point, 2·70 to 2·75 pts.; and 100 pts. ether dissolve 0·26 pt. lophi 0·33 at 20°, and 0·32 at 21°. Of an indifferent substance, having n sition of lophine, and formed, together with the latter, by the decomp chlorate of hydrobenzamide at 160°–200° (p. 183), 100 pts. absolute 0·07 pt. at 16°, and 0·33 to 0·37 pt. at the boiling point; and 100 boiling point dissolve 0·69 to 0·74 pt. of the same substance.

Decompositions.—Lophine boiled with *nitric acid* forms nitrolop It is dissolved by *bromine*, without evolution of vapours of hydrobro the mass is dissolved in ether, and the solution mixed with alcohol spontaneous evaporation, beautiful yellow prisms with rectangular b these crystals give off bromine when heated, and, when water is p turn white and fall to powder (Laurent). Lophine in contact wit does not form any substitution-compound not even when the two together to 100° in a sealed tube for several weeks. A portion of th is decomposed into alcohol and hydriodic acid, which combines w (Gössmann and Atkinson.)

The lophine-salts are for the most part insoluble in water, and in alcohol.—They are rather unstable, having a tendency when recr up part of their acid and form basic compounds; this is particularly sulphate. (Gössmann and Atkinson.)

Hydriodate of Lophine, $C^{21}H^{16}N^2.HI$, is prepared like the hydrochlo lises readily in large needles, which are more soluble in alcohol an hydrochlorate. From a very acid solution, it separates in granular solves very easily in iodide of ethyl. In other respects it resembles t (Gössmann and Atkinson.)

Hydrochlorate of Lophine, $C^{21}H^{16}N^2.HCl$, separates quickly on coo tion of lophine in boiling alcohol containing hydrochloric acid. sufficient quantity of boiling alcohol be mixed with such a quantity no immediate precipitate is formed, the liquid on cooling yields well d

according to the nature of the operations to be performed, and of th distilled in these vessels.

When vapours of watery liquors, and such as are not corrosive, it is sufficient to surround the joining of the receiver to the nose of the retort, with slips of paper or of linen covered with flour-paste. slips of wet bladder may be conveniently used.

When more penetrating and dissolving vapours are to be retaine employed of quicklime slacked in the air, and beaten into a liquid p eggs. This paste is to be spread upon linen slips, which are to b the joining of the vessels. This lute is very convenient, dries eas and sufficiently firm. Vessels may be formed of it hard enough to the wheel.

Lastly, when acid and corrosive vapours are to be retaine recourse to the lute called *fat lute*. This lute is made by forn some dried clay finely powdered, sifted through a silken sieve, an water, then beating this paste well in a mortar with boiled linse which has been rendered drying by litharge dissolved in it, and painters. This lute easily takes and retains the form given to i rolled into cylinders of a convenient size. These are to be applied, to the joinings of the vessels, which ought to be perfectly dry, beca ture would prevent the lute from adhering. When the joinings a this fat lute, the whole is to be covered with slips of linen spread wit whites of eggs. These slips are to be fastened with packthread. necessary to keep on the fat lute, because this latter remains soft, an solid enough to stick on alone.

Gutta percha may be united to glass, in tube apparatus, by fusin at the point of junction by means of a hot iron knife-blade.

Fine porcelain clay, mixed with a solution of borax, is well adapt the part received into an aperture being smeared with it.

LUTEOLIN. The yellow colouring matter of weld (*Reseda lut* isolated by Chevreul (J. Chim. méd. vi. 157), and has been mo and analysed by Moldenhauer (Ann. Ch. Pharm. c. 180) and by S and Paraf (*ibid.* Suppl. i. 139). Moldenhauer prepares it by exha alcohol, distilling off the alcohol from the extract; then washing wit the residue; exhausting it with ether; dissolving the residue left c ethereal solution in alcohol; adding a larger quantity of water boiling point; filtering hot; and leaving the filtrate to cool. Th purified by recrystallisation from boiling very dilute spirit containin alcohol. Schützenberger and Paraf exhaust the plant with alcoh extract with water, and heat the precipitate with water to 250° in s the luteolin then crystallises on the sides of the vessel on cooling, an by two crystallisations from superheated water.

Luteolin crystallises from solution in boiling dilute alcohol, also fr solution in dilute sulphuric or acetic acid, in yellow four-sided ne radiate groups; it may also be obtained in needles by careful sublin at 320° with partial decomposition, to a black-brown mass. It i slightly bitter, astringent taste; dissolves in 14,000 pts. of cold and 5 *water*, in 37 pts. *alcohol* [at what temperature?] and in 625 pts. of litmus paper slightly, and unites with *metallic oxides*. It dissolves colour in *caustic alkalis* and *alkaline carbonates*, remaining in the pu ammoniacal solution is evaporated (Moldenhauer). By prolon *ammonia*, it is completely dissolved, forming a deep yellow solu on evaporation a dark coloured residue which gives off ammonia w potash (Schützenberger and Paraf). In cold dilute *acids* it soluble; more easily in cold *concentrated sulphuric acid*, forming from which it is separated by water without alteration. It dissolves concentrated *hydrochloric acid*, more easily in warm concentrated nearly insoluble in that acid when cold. Dilute *nitric acid* acts u heated; strong nitric acid dissolves it with deep red colour, t decolorised by prolonged boiling, with formation of oxalic acid (Heated to 200° with *phosphoric anhydride*, it yields a red substanc with violet colour in ammonia (Schützenberger and Paraf). *chromate of potassium* and *sulphuric acid*, it yields formic acid. It d a solution of *gelatin*, but forms a green precipitate with a very dilute *chloride*, and colours a concentrated solution brown-red (Moldenha to Chevreul, the aqueous extract of weld forms beautiful yellow preci

Mercuric salt of Lutidine, $C^7H^9N.HgCl^2$. This salt separates fro alcoholic solutions of lutidine and mercuric chloride, as a white from dilute solutions it is gradually deposited in radiating crystal boiling water, with partial decomposition; more freely, and wit boiling alcohol. (Anderson.)

Palladium-salts.—The chloropalladite of β-lutidine, $2(C^7H^9N$ tained, as a nearly solid mass of garnet-red prisms, on leaving a m hydrochloric acid, and chloride of palladium, to itself for four days. a long time to 100°, it is decomposed, 1 at. hydrochloric acid being of the salt, and leaving the compound:

$$C^{28}H^{28}N^4Cl^6Pd^2 = 2(C^7H^9N.HCl).PdCl^2.2C^7H^9N.Pd$$

The *chloride of palladio-β-lutidyl-ammonium*, $N^2\left\{\begin{matrix}2(C^7H^9)'' \\ Pd''\end{matrix}\right\}Cl^2$, t the last-mentioned substance, is easily obtained by acting on chlori solution with β-lutidine. This base is not easily soluble, and pu (Williams.)

On mixing solutions of hydrochlorate of *lutidine* and chloride of similar in concentration to those above employed, no crystals we time that the contents of the vessel containing the β-lutidine ha and even after a month's repose, the quantity obtained was much β-lutidine.

Platinic salts.—The *chloroplatinates* of both bases hav $2(C^7H^9N.HCl).PtCl^4$, and crystallise in rectangular tablets; but exhibits the same superior facility of crystallising that is observed i gold- and palladium-salts. The presence of hydrochloric acid in exc the formation of the lutidine-salt (Anderson); but Williams finds case with the β-lutidine-salt, a mixture of the hydrochlorate of β-lut chloride and a large excess of hydrochloric acid instantly becoming

Decomposition of the Platinic salts by boiling.—Chloroplatinate o to decompose the instant the solution enters into ebullition, an insol beginning to deposit, and rapidly increasing in quantity. After

this salt has the composition of *tetrahydrochlorate of platino-lutidine*, β

The solution of chloroplatinate of lutidine, on the other hand, active boiling before any deposit began to form; and even after sev the deposit was very small.

Platinous salts.—When equal weights (1 grm. each) of platin β-lutidine were mixed in an apparatus surrounded with a non-condu temperature rose from 16° to 84°, and a hard brittle product was almost exactly in composition with the formula $2C^7H^9N.PtCl^2$. treated with platinous chloride under exactly the same condition rose two degrees higher; but the product, instead of becoming a remained of the consistence of treacle.

Substitution-derivatives of Lutidine.

Ethyl-β-lutidine.—A mixture of 1 vol. β-lutidine and 2 vol. iodid a sealed tube to 94° for three minutes, solidified on cooling to a mass *of ethyl-β-lutidine*, $C^7H^8(C^2H^5)N.HI$.—The *platinum-salt* prepared usual way, crystallises in superb orange-coloured fronds, containin $PtCl^4$. This salt when boiled with water turns black, and deposits two days' boiling, it yielded 27·5 per cent. of the metal, the original sa per cent. (Gr. Williams.)

Ethyl-lutidine.—A mixture of lutidine and iodide of ethyl in the heated to the same temperature for the same time, showed no signs on cooling. It required an hour's digestion to effect combination; hours, only half the product had crystallised, the rest remaining in t (Gr. Williams, Proc. Roy. Soc. xii. 311.)

Methyl-β-lutidine, $C^8H^{11}N = C^7H^8(CH^3)N$.—β-lutidine mixe methyl, becomes heated, and forms *hydriodate of methyl-β-lutidine*, in water and alcohol, but nearly insoluble in ether. Its alcoholic s to a syrup, remains liquid if left at rest; but on touching it, bea shoot through the liquid, which soon becomes completely solid. T $2(C^8H^{11}N.HCl).PtCl^4$, forms crystals containing 30·29 per cent. plat liams, Ed. Phil. Trans. xxi. [2] 317.)

Fat occurs in lymph only in small quantities, and for the most part form; in the lymph of the horse, Nasse found 0·0088 per cent. of free f per cent. of alkaline salts of fatty acids; while in human lymph, Ma berg found 0·264 per cent. of a pale reddish fat.

The lymph also contains lactates.

In horses' lymph, Nasse found 0·0755 per cent. of extractive in alcohol, and 0·9877 per cent. soluble in water only; while, accor and Schlossberger, the whole of the extractive matters amount to Nasse was unable to detect urea in the lymph of the horse.

Mineral constituents.—In lymph, as in all the animal fluids, chlorid the preponderating mineral constituent: in horses' lymph, it amounts, acc to 0·4123 per cent. Alkaline carbonates were found by Nasse in the quantity being estimated at 0·056 per cent.; but Geiger failed in dete the ash of the solid constituents of the lymph, however, the latter found of alkaline carbonates. The presence of ammoniacal salts, which by Nasse, has been definitely established in horses' lymph by Geiger and Nasse found that horses' lymph is comparatively rich in sulphuric aci in it pre-formed; he estimates the quantity of sulphate of potassiu cent. Alkaline phosphates occur only in very small quantities. salts, with a small quantity of ferric oxide (arising probably from th few blood-corpuscles), were found by Nasse to amount to only 0·031 per lymph.

The quantity of water in lymph appears to be very variable, but n in the blood-plasma. In human lymph, Marchand found 96·926 per cent. found 92·436 per cent. water; in the lymph of horses, the quantity ha vary from 92·5 to 98·37 per cent.

Nasse has instituted an interesting comparison (based on direct an the composition of the lymph and of the blood-serum of the horse, from w that the individual salts stand to one another in precisely the same liquids, although their absolute quantity is very different, on account o tively larger proportion of water in the lymph.

There are also considerable differences in the proportions in which t stituents stand to the organic matters in the two liquids: while 10 correspond to 1036 pts. of organic matters in the blood-serum, the rati is as 100 to only 785. According to Marchand and Colberg, human organic and inorganic matters in nearly equal parts. (*Lehmann's Physiolo* translated by Day, ii. 299.)

LYNCURION. A Greek name for Amber.

M.

MACE is the *arillus* or envelope of the fruit of the nutmeg (*Myris* It forms a somewhat thick, tough, unctuous, reticulated membrane, o brown or orange colour; has a somewhat more agreeable odour than warm and pungent taste, and is used as a condiment in cooking.

Mace contains two oils, one of which is unctuous, bland, and of the butter; the other, which is obtained by distillation with water, is thinn By cohobating four times, 4·7 per cent. oil may be obtained (Hoff Pharm. xliii. 296); from old mace, 4·1 per cent. (Bley, *ibid.* xlviii. 94) parent and colourless; of specific gravity 0·931; smells strongly of m burning aromatic taste. It forms a permanent liniment with aqueous a

MACLE is the name given to certain spots in minerals of a deepe rest; sometimes proceeding from difference of aggregation, sometimes fr of a foreign substance: clay-slate, for example, may be macled with iro

MACLES. Twin-crystals (ii. 159).

MACLURIN. Syn. with Morintannic Acid (p. 1049).

MADDER. *Garance. Krapp.*—The root of *Rubia tinctorum*, e in dyeing for the production of a variety of colours, namely, red, pink, and chocolate. Other species of *Rubia* yield similar colouring matters, an as dyeing materials; viz. *R. Mungista*, or *Munjeet*, which grows in th regions of Hindoostan, and is used in that country for producing the red figures seen in the chintz calicoes of the East Indies; and *R. peregrina*, vated in the Levant, where it is called *Alizari*, and imported into this the name of *Turkey-roots*; but *Rubia tinctorum*, or *dyers' madder*, is t

thrives best in a warm climate, and is grown extensively also in Alsace and in Naples; in the north of Europe it ion.

ıave a peculiar smell, and a taste between bitter and sweet. ıely, being sometimes yellow, sometimes orange-red, reddish- e more or less hygroscopic; so that even when closely packed wder, they slowly attract moisture, increase in weight, and at lent condition, forming a firm coherent mass. Some kinds e of Alsace and Holland, when mixed with water and left to ive a thick coagulum or jelly—an effect which does not take ith Avignon madder. The madder of Avignon contains so much effervesce with acids. The herbaceous parts of the plant, attle, are found to communicate a red colour to their bones. es which madder presents, as a dye-stuff, are the following:— ing, according to the mordants and the method of treatment, t colours and shades; such as black; red of different kinds, o a bright red and delicate pink, besides the peculiar colour o purple of various shades, from a dull reddish-purple to a lilac, as well as chocolate of all shades.—2. Its colouring inity for cotton fibre, and a great affinity for mordants; so secure a good white on the parts of the tissue to which no .—3. The compounds which its colouring matter or matters ss an unusually stable character; so that they may be ex- ment to the colour, to the action of various agents for the odifying the shade.

ion of Madder. There is probably no subject connected ich has given rise to so much discussion as the composition al nature of the colouring matters to which it owes its valu- ect has engaged the attention of a great number of chemists, cially mentioned, Robiquet and Colin, Kuhlmann, Gaulthier unge, Schunck, Schiel, Higgin, Debus, Strecker, Rochleder, Nevertheless, our knowledge of madder, as compared with other colouring principles, is still confused and uncertain. sts (Sacc, for example) and many manufacturers, madder principle, while most others admit the existence of at least urin. Moreover, according to some chemists, the colouring ready formed; whereas others suppose that fresh madder generating substance, which subsequently, by a kind of fer- e colouring matter properly so called: the latter, which is be based on the most trustworthy experiments.

cial madder is exhausted with boiling water, a dark-brown l, having a taste between bitter and sweet. On adding d to this liquid, a dark-brown precipitate is produced; while ecomes clear, and appears of a bright yellow colour. The zarin, purpurin, rubiacin, two resinous colouring matters, active matter, and a peculiar nitrogenous substance. The recipitate contains the bitter principle and the extractive as sugar, and salts of potassium, calcium, and magnesium. can be detected in the watery extract. After the madder sted with boiling water, it appears of a dull-red colour. It colouring matter, which cannot, however, be extracted with lis, since it exists in a state of combination with lime and ounds which are insoluble in those liquids. If, however, ith boiling dilute hydrochloric acid, that acid dissolves a , alumina, and sesquioxide of iron, as well as some phos- ium, which may be discovered in the filtered liquid; and ing well washed, be treated with caustic alkali, a dark-red ives with acids a dark reddish-brown precipitate of alizarin, nd pectic acid. The portion of the madder left after treat- ids, and alkalis, consists almost entirely of woody fibre.

hown to exist in ordinary madder, the most important are l purpurin, which are in fact the essential red colouring They were discovered by Robiquet and Colin, to whom rst memoir of any importance relating to the chemistry of [2] xxxiv. 225.)

Digitized by Google

Alizarin, the *Lizaric acid* of Debus, *Madder-red* of Runge, *rouge* of Gaulthier de Claubry and Persoz, was obtained by Robiqu sublimate, in beautiful reddish-yellow needles; but the mode of prep adopted left it uncertain whether the alizarin pre-existed in madde of decomposition of some other body produced by heat.

It may, however, be extracted from ordinary madder, as used b action of solvents, and obtained in crystals without sublimation: I in ordinary madder may be inferred (see i. 114; and for detai *Gmelin's Handbook*, xiii. 326, and xiv. 130). Its composition cann definitely established. Wolff and Strecker's formula, $C^{16}H^6O^3$, is n with the relation of alizarin to chloronaphthalic acid, $C^{10}H^5ClO^3$, b pounds being converted, by the action of nitric acid, into phthalic a formula, $C^6H^4O^4$, appears to explain more clearly the formation of al (p. 745): it must be remembered, however, that the formula of rub means well established. Alizarin is very little soluble in water, more but nearly insoluble in aluminium-salts. Its alkaline solutions hav or purple colour, and it forms lakes of various colours with the metallic oxides.

Purpurin, the *Madder-purple* of Runge, *Matière colorante ros* Claubry and Persoz, *Oxilizaric acid* of Debus, is extracted from m processes as alizarin, and separated from it by its superior solubili It bears considerable resemblance to alizarin, yielding a crystallin heated, and being very sparingly soluble in water, but more s The properties by which it is distinguished from alizarin, are its boiling alum-liquor, forming a solution of a beautiful pink co fluorescence; and secondly, the colour of its alkaline solutions, which bright red; whereas alizarin forms violet solutions with alkalis. might, however, be produced by the admixture of some foreign substa and accordingly some chemists, as already observed, do not rega distinct substance, but attribute all the colouring power of madder to are, however, other characters which show beyond doubt that purpu substance: viz.—1. Its decomposition when exposed to the air in alk colour of the liquid then changing from bright red to reddish-yellow, a appearing almost entirely, after which purpurin can no longer be disco tion, whereas alizarin suffers no such decomposition (Schunck' properties. Stokes has shown that when a solution of purpurin is exa the spectrum which it exhibits is totally different from that which is manner by alizarin. (See LIGHT, p. 638; also PURPURIN.)

Considerable difference of opinion likewise exists as to the relative and purpurin as dyeing materials. According to Robiquet and Schun most permanent madder-colours are produced by alizarin; whereas Ru are of opinion that the liveliest tints are produced by purpurin, and t likewise plays the principal part in the manufacture of Turkey-red. Kopp, on the other hand, the real basis of Turkey-red is alizarin; and that purpurin, though it dyes mordanted fabrics perfectly, does not so great a degree of stability, and has not so great an affinity for oiled

From Schunck's experiments, it appears that all the usual madde obtained by means of alizarin, and that the colours so produced are as as ordinary madder-colours are after a long course of treatment wit They are likewise equally fast, and quite equal to ordinary madder power of resisting decomposition by soap, alkalis, &c.

In short, the final result of dyeing with madder and its preparatio simply the combination of alizarin with the various mordants employe be shown, indeed, that the finer madder-colours contain little besides a nation with the mordant. If, for instance, a few yards of 'madder-pink c with hydrochloric acid to remove the alumina of the mordant, then treated with caustic alkali, a violet solution is obtained from which yellow flocks consisting of almost pure alizarin. Purpurin, on the oth to have almost entirely disappeared from all madder-colours which jected to a long course of after-treatment; a result quite in accordance w mentioned of the decomposition of purpurin in alkaline solution on ex (Schunck.)

Madder likewise contains certain yellow colouring matters: but th not positively injurious, in the process of dyeing. **Rubiacin** is a ye colouring matter, coinciding in most of its properties with the *madder-* It is only slightly soluble in boiling water, but dissolves more freely in

, on cooling, in greenish yellow lustrous scales and needles. It osition in strong sulphuric and in boiling nitric acid, and with Its compounds with metallic oxides are mostly red. When ution of ferric chloride or nitrate, it dissolves entirely, yielding which gives with hydrochloric acid a flocculent precipitate of

olouring matters already mentioned (p. 742), one is a dark- body, very soluble in alcohol, and melting at a little above ish-brown powder, less soluble in alcohol than the preceding. ters, together with rubiacin, constitute probably the tawny tter of madder mentioned by the older chemists. They do nsity of the colours dyed with madder, and exert a very pre- ity of the dyes. If printed calico be dyed with a mixture of ese three colouring matters, the colours are found to be both ul than when alizarin is used alone. The red acquires an rple a reddish hue, whilst the black is less intense, and the n white have acquired a yellowish colour. The effect of these herefore, be counteracted as much as possible by preventing g in the dye-bath, or from attaching themselves to the fabric. tituents of madder are also for the most part injurious in dye- state in which it exists in the root, is probably an indifferent uence of the ease and rapidity with which it passes into pectic judicially in dyeing, by combining with the mordants and ing up the colouring matter.

ter of madder, when in an unaltered state, produces no inju- ut by the action of oxygen, especially at elevated tempera- colour, and then contributes, together with the rubiacin and s, to deteriorate the colours, and sully the white parts of the m dirty reddish-brown tint which a piece of calico exhibits, nprinted portions, after having been dyed with madder: the ne of the objects of the after-treatment with soap and other s of manufacturing garancin, this substance is partly decom- the subsequent washing: and this explains, in a great mea- nd brilliancy of garancin colours, as compared with madder natter, when pure, has the appearance of a yellow syrup, like water and in alcohol, and is not precipitated from its aqueous metallic salt; but the solution, if evaporated in contact with rown, and then gives an abundant brown precipitate with ous solution mixed with hydrochloric or sulphuric acid, and l deposits a dark-green powder. Hence this extractive matter genin by Schunck, rubichloric acid by Rochleder. The and the madder-yellow of Runge appear to be mix- atter with a bitter principle.

in madder is probably glucose: it has not hitherto been sed state; but it yields alcohol and carbonic acid by fer- sugar. The woody fibre which remains after madder has d by the action of various solvents (p. 742), always retains a h tinge, from the presence of some colouring matter which oved, and seems to adhere to it in the same way as it does to cotton.

ituents of madder-root have been analysed by H. Köchlin 4) and K. Moy (*ibid.* liv. 346); those of the seed by Schiel).

Formation of the Red Colouring Matters.—The extraction of alizar from madder by the action of solvents shows that these colouring ma formed in madder in its ordinary state, as used by the dyer. But i question whether they exist in the root while growing or when n whether they are formed by any subsequent process of chemical chan long been known that when ground madder is kept tightly packed stantly improves in quality for several years, after which it again det was always supposed that this effect was due to some process of s The real nature of the change, however, remained for a long time unk supposes that the change which goes on consists in the conversion of purin; but this would constitute anything but an improvement in q colours produced by purpurin are in most respects inferior to those of a this, alizarin is a body not easily decomposed, unless exposed to th potent agents; and any portion of it once formed in the root, would p action of air and moisture for a very long period of time, if not entir of Manchester states, as the results of his experiments on this subject, in madder a peculiar albuminous ferment, which, by acting on the xa to the formation of colouring matter; and that this process takes plac even during the short period of time occupied in dyeing. This vie firmed in its main features by the experiments of Schunck.

That the whole of the colouring matter of madder does not exist rea article as used by the dyer, may be rendered evident by a simple madder be exhausted with cold water, the clear watery extract does alizarin or other colouring matter, since these are almost insolubl Nevertheless, the extract when gradually heated is found capable of dy way as madder itself. If made tolerably strong, it possesses a deep y a very bitter taste; but if it be allowed to stand in a warm place fo gelatinises, and the insoluble jelly which is formed is found to possess tinctorial power of the liquid, while the latter has lost its yellow c taste. Hence it may be inferred that the substance which imparts t bitter taste and yellow colour, is capable of giving rise to the forma portion of colouring matter. By extracting madder with boiling wate gelatinisation or coagulation is prevented, and the extract retains its y bitter taste; a proof that the coagulation observed in the extract with result of some process of chemical change which is arrested when th sufficiently raised. When the extract is agitated with a little animal ch absorbs the bitter principle, and gives it up again to boiling spirits o evaporation leaves it in an almost perfect state of purity. In this obtained a substance to which he has given the name of Rubian, principal characteristics are these:—It is amorphous and shining like yellow colour and an intensely bitter taste, is easily soluble in water is not a colouring matter in the practical sense of the word, for it g in dyeing only the faintest shades of colour. But if its watery solutio sulphuric acid and boiled, it gradually deposits a quantity of insolu and becomes almost colourless. These flocks, after being well washe dye exactly the same colours as alizarin. In fact they contain aliza gives the reactions of sugar. Taking this fact into consideration, it to give an account of the principal change which takes place in the p facturing garancin. It is evident that during this process, the easil becomes converted into the difficultly soluble alizarin, that there is in an actual formation of colouring matter which is added to that already root. A similar change takes place when caustic alkali is used in pl A solution of rubian on being mixed with caustic potash or soda, simp on being boiled, it becomes dark purple and deposits a purple powde chiefly of a compound of alizarin with alkali, insoluble in caustic lye. also decomposes rubian with great facility; but in order to effect its is not indifferent what ferment is taken; a peculiar ferment is essentia A solution of rubian may be left for several days in contact with ye albumin, casein, emulsin, &c., without showing any sign of change. of madder with cold water be mixed with a large excess of alcohol, flo colour are precipitated, which, after being well washed with alcohol, a sist chiefly of an azotised principle called Erythrozym, which exert powerful decomposing effect on rubian. If some of this substance a watery solution of rubian, and the mixture be left to stand at th perature, the rubian is found after a few hours to be as completely

a. Formation of alizarin ($C^{14}H^{10}O^4$ according to Schunck):

$$C^{28}H^{34}O^{15} = 2C^{14}H^{10}O^4 + 7H^2O.$$

b. Of verantin and rubiretin:

$$C^{28}H^{34}O^{15} = C^{14}H^{10}O^5 + C^{14}H^{12}O^4 + 6H^2O.$$

c. Of rubianin and glucose:

$$C^{28}H^{34}O^{15} + H^2O = C^{22}H^{24}O^{10} + C^6H^{12}O^6.$$

d. Of rubiadin and rubiafin:

$$C^{28}H^{34}O^{15} + 2H^2O = C^{16}H^{14}O^5 + 2C^6H^{12}O^6.$$

Or rubiadin and rubiafin may be considered as products of the further metamor of rubianin:—

$$C^{22}H^{24}O^{10} + H^2O = C^{16}H^{14}O^5 + C^6H^{12}O^6.$$

It appears, then, that rubian undergoes, not one, but three different proces decomposition when acted on by acids, alkalis, or ferments; that the formation of is connected not with that of alizarin, but with that of rubianin and its allies, an in fact there is no reason why only one of these processes should not take place exclusion of the others; why, for instance, rubian should not be so decomposed yield alizarin alone, without any of the accompanying bodies, which are from this of view, not only a source of loss, but also prejudicial in practice.

The formation of alizarin and of the other products of rubian above mentioned not depend upon oxidation. Nevertheless, according to Schunck, rubian does a partial oxidation when its aqueous solution, mixed with an alkali or alkaline is exposed to the air, the product formed being rubianic acid, $C^{52}H^{30}O^{27}$, (or p $C^{52}H^{30}O^{28} = C^{52}H^{30}O^{14}$). Its formation may perhaps be represented by the equ

$$\underset{\text{Rubian.}}{C^{28}H^{34}O^{15}} + O^5 = \underset{\text{Rubianic acid.}}{C^{26}H^{30}O^{14}} + 2CO^2 + 2H^2O.$$

It is a true glucoside, and is resolved by the same agents which effect the deco tion of rubian into alizarin and glucose, no secondary products making their a ance; perhaps thus:

$$\underset{\text{Rubianic acid.}}{C^{26}H^{30}O^{14}} + 2H^2O = \underset{\text{Alizarin.}}{C^{14}H^{10}O^4} + 2\underset{\text{Glucose.}}{C^6H^{12}O^6}.$$

For further details respecting all these products, see RUBIAN.

Use of Madder in Dyeing. The chief use of madder is in cotton-dyei calico-printing. In woollen-dyeing it is not so much employed, especially i country, only the ordinary woollen goods being dyed red with it; the colour is bright as that obtained with cochineal or lac, although more permanent and c Silk is seldom dyed with madder, because cochineal affords brighter tints.

The series of operations usually adopted for printed calicoes is as follows:—

1. The calico having been singed and bleached, the mordant is printed on; n '*red liquor*' (acetate of aluminium containing a small quantity of sulphate) for pink; '*iron liquor*' (ferrous acetate) for violet, purple, or black; and a mixture with *red-liquor* for chocolate.

2. The printed cloth is hung up with free access of air for about two days. this process of "ageing," the mordant undergoes important changes, and becom great extent insoluble, and therefore fixed in the cotton: *red-liquor* parts with part of its acetic acid, and its alumina remains as a highly basic sulphate; *iron* absorbs oxygen and loses acetic acid, and is thus converted into a basic ferric Of late years, a "rapid ageing process" has come into extensive use; it con passing the printed calico through a heated chamber, the atmosphere of which exactly saturated with water-vapour. This process is frequently completed in half an hour, but the time required for it, as well as for the ordinary ageing varies with the amount of mordant upon the cloth.

3. The next operation is called "dunging," and consists in passing the cloth t a hot mixture of cow-dung and water. During this process, superfluous por the mordant, which would otherwise get detached from the cloth during the dye would be precipitated in combination with colouring matter upon the unprinted are removed (perhaps in combination with organic constituents of the bath), remainder is converted more or less completely into phosphate. For a good years past, the use of cow-dung in this process has been to a great extent sup by that of an artificial preparation known as "dung substitute," first introdu Mercer, the essential constituents of which are alkaline phosphates and arsenates DYEING, ii. 353.)

4. Steeping in the madder-bath, which is kept lukewarm at first, and gr raised to the boiling heat.

Robiquet have shown by experiment that, in dyeing with pure addition of lime is rather injurious than otherwise, as it weakens adding to their durability. On the other hand, the addition of rubi colouring matters, or of pectic acid to alizarin was found to be very then acquiring an orange, and the purple a reddish hue, while brownish, and the white parts of the fabric assumed a yellowis effects disappeared completely as soon as the foreign colouring ma saturated with lime, the tinctorial power of the alizarin then reap original intensity. Too great a quantity of lime must however be take hold of the alizarin itself, and prevent it from uniting with th

Preparations of Madder. Since madder contains a variety impair the brightness and permanency of the colours produced by rin, it follows that the process of dyeing with it must be greatl previous removal of these substances. This object is attained by t sulphuric acid, which destroys the rubiacin, resinous colouring matte tractive matter, &c., and at the same time, by its action on the rub the madder, increases the quantity of alizarin and purpurin. M produces dyes which require less clearing than ordinary madder is this further advantage in its use, that nearly all the colouring ma is available for dyeing, whereas when crude madder is employed, n colouring matter remains in the residue unutilised. These conside the use of the following preparations of madder:

1. **Sulphuric Charcoal** (*Charbon sulphurique*).—This na Robiquet to a product which he obtained by treating pulverised siderable quantity of rather strong sulphuric acid for several hours water, filtering, washing, and drying the residue. It dyes strongl fine colours; but being difficult and costly to prepare on the large sc has been abandoned, excepting for the preparation of coloring, a into commerce by MM. Lagier and Thomas, and obtained by exh ric charcoal with alcohol and distilling the solution to the consiste

2. **Garancin**, first prepared by Lagier, Robiquet, and Coli similar manner to sulphuric charcoal, excepting that a smaller added (less than a third of the weight of the madder), and the mi diluted with water and boiled for a longer time. The product is ground with a small quantity of chalk or sodic carbonate to neut may be retained by the woody fibre. Madder yields from 33 to 36 Garancin colours are regarded as somewhat less stable than tho from madder; but, if the garancin be well prepared, the colours ar brilliant, and the white ground remains intact. The violets which ever not quite satisfactory, and to obtain a rose colour with it is ve

3. **Pincoffin**, or *Alizarine commerciale*, introduced by Messrs. Manchester, is a garancin prepared and washed with the greatest care, as possible, and heated above 100° by high pressure steam, whereb of brown colouring matter is destroyed or rendered inert. This pure and bright violet tints without requiring clearing, and the oth with it are equally satisfactory.

4. **Garanceux.**—This is a product obtained by treating the dye-houses, which, as already observed, still retains a considerable matter, with sulphuric acid, then filtering, washing, drying, substance thus obtained still dyes tolerably well, and may be used patterns not containing rose or violet tints.

5. **Flowers of Madder** (*Fleur de Garance*) is the name given madder first prepared at Avignon by MM. Julien and Rocquer. pended in water containing a small proportion of acid, partly to sa nates, partly to render the colouring principles less soluble. It is the water for some hours, during which time alizarin and purpu become insoluble, and sometimes a true fermentation is set up. carefully washed, so as to remove only the more soluble matters. being strongly charged with sugar, are subjected to vinous fe subsequently distilling them, a considerable quantity of alcohol is yields about 50 per cent. of this product, which, being free from gu bodies, and especially from the brown colouring principle which yield much finer colours than madder itself. More than half the cultivated at the present day is converted into flowers of madder

6. **Madder Extracts.**—All the products above mentioned whole of the woody fibre of the root, an impurity which prevents

nagnesium may be separated by precipitating the former with
. 155).
trontium, magnesium is separated by *sulphuric acid*; from
mmonium, with addition of chloride of ammonium, to prevent the
esia. When, however, the quantity of calcium present is very
e magnesium, this mode of precipitation does not give exact
according to Scheerer (Ann. Ch. Pharm. cx. 36), to convert
nates; dissolve the sulphates in water; carefully add alcohol
ent turbidity is produced; leave the liquid to itself for a few
sulphate of calcium will be completely precipitated, together
sulphate of magnesium; wash the precipitate on a filter with
qual volume of water; then redissolve t in water, add hydro-
d precipitate the lime with oxalic acid and ammonia.
als, magnesium may be separated by converting the bases into
ryta-water. The magnesia is then precipitated in the form of
lphate of barium. The precipitate, after washing, is digested
d, which extracts the magnesia in the form of sulphate; and
e alkalis together with the excess of baryta, is also treated with
cipitates the baryta, and converts the alkalis into sulphates.
e separated from the alkali-metals by means of *mercuricoxide*,

Digitized by Google

The solution, from which all metals except those of the alkalis and magnesium been removed, and which must contain no fixed acid, is digested with excess of divided mercuric oxide; the whole evaporated to dryness, and the residue hea drive off the mercury. The magnesium then remains as magnesia, and the alka be washed out with water.

Chancel (Compt. rend. 194) recommends the following method. The magn precipitated from the solution containing sal-ammoniac and free ammonia, by *pho of ammonium;* the filtrate is evaporated to dryness; the residue carefully ign expel ammoniacal salts; then redissolved in water; and the solution is mixe nitrate of silver and a slight excess of carbonate of silver. After filtering phosphate of silver (and chloride, if the alkalis existed in the solution as chloride excess of silver is removed from the filtrate by hydrochloric acid, and the alka estimated as chlorides.

4. *Atomic Weight of Magnesium.*—Berzelius found that 100 pts. of ma dissolved in pure sulphuric acid and ignited, gave 293·85 of sulphate of magn $Mg''SO^4$, whence the atomic weight of magnesium would be 25·24, a result to according to later experiments.

Scheerer (Pogg. Ann. lxix. 135), by determining the quantity of sulph barium produced from a given quantity of sulphate of magnesium, found for mag the number 24·2. The results of Svanberg and Nordenfeldt (J. pr. Che 473), obtained by the decomposition of oxalate of magnesium ($Mg''C^2O^4.2H^2O$ it 24·7; those obtained by converting a known weight of magnesia into s gave it as 24·74; whilst those of Marchand and Scheerer (Ann. Ch. Pharm 219), obtained by igniting the native carbonate (magnesite), gave the number Dumas (Ann. Ch. Phys. [3] lv. 129) attempted to determine the atomic we magnesium by precipitating the chloride with nitrate of silver, but he fou greatest difficulty in obtaining the chloride free from magnesia. The mean of experiments gave $Mg'' = 24·6$.

The mean of all these results is 24·32, but those of Marchand and Schee generally regarded as the most trustworthy. Moreover Scheerer has lately sho his method of separating calcium and magnesium above given (p. 753), th specimens of magnesite used by himself and Marchand in their determinatio tained small quantities of calcium not previously detected. He therefore co that the number 24·04 found in those experiments was rather above than be truth. On the whole, then, the atomic weight of magnesium may be regarded

MAGNESIUM, FLUORIDE OF. Obtained as a white tasteless pow treating the carbonate with hydrofluoric acid, or mixing the sulphate with fluo potassium. It is insoluble in water and nearly insoluble in acids.

MAGNESIUM, FLUOBORIDE OF. See Borofluorides (i. 634).

MAGNESIUM, FLUOSILICIDE OF. See Silicofluorides.

MAGNESIUM, IODIDE OF. Obtained by evaporation of its solutio difficultly crystallisable hydrate, which deliquesces in the air, and when heate off hydriodic acid and leaves pure magnesia.

MAGNESIUM, NITRIDE OF. Mg^3N^2.—Deville and Caron (Comp xliv. 394), by distilling impure magnesium, obtained a black residue, and a di of magnesium covered with small transparent needles, which easily decompose formation of magnesia and ammonia, and therefore contained a nitride of magn Briegleb and Geuther (Ann. Ch. Pharm. cxxiii. 228) have obtained th compound, in the amorphous state, by igniting metallic magnesium in ammoni nitrogen gas; the latter method giving the purest product. Nitride of mag thus prepared is a greenish-yellow amorphous mass, becoming brownish-yello hot. Heated in dry oxygen gas, it oxidises to magnesia, with vivid incandescen is decomposed by air and water, the reaction in the latter case being violent to make the water boil. Acids both dilute and concentrated, with the excep strong sulphuric acid, form ammonium- and magnesium-salts, even in the cold; sulphuric acid, only when heated, and with evolution of sulphurous anhydride nitride heated in hydrochloric acid gas, yields chloride of ammonium and chlo magnesium; in sulphydric acid, the corresponding sulphides. Carbonic anhydr dry carbonic oxide decompose it, at the heat of a strong air-furnace, with sep of carbon and formation of cyanogen. When vapour of pentachloride of phosph passed over nitride of magnesium heated in a stream of nitrogen, the nitride verted into a greyish-white substance, probably P^3N^5, according to the equation

$$6PCl^5 + 5Mg^5N^2 = 15MgCl^2 + 2P^3N^5.$$

Magnesium-ethyl forms a finely-crystallised double salt with iodide probable formula, MgC^2H^5I. (Wanklyn.)

MAGNESIUM-METHYL is produced by the action of magne of methyl in a manner similar to the above. It is likewise a mobile liquid, which instantly takes fire in the air, and quickly decomposes wa tion of marsh gas and separation of magnesia. (Cahours.)

MAGNETIC IRON ORE. Native ferroso-ferric oxide (iii. 337)

MAGNETIC PYRITES. Ferroso-ferric sulphide (iii. 401).

MAGNETISM. It has been known from very early times, that t oxide of iron, or ferroso-ferric oxide (Fe^3O^4) possesses, at certain point called poles, the power of attracting small pieces of iron. The Gree mineral the name of *magnetes* (μάγνητης), from the village of Magn near which it was found in considerable quantity: hence the name M plied to the branch of science which treats of this peculiar kind of att the various phenomena related to it.

The attractive power of the natural magnet may be communicated t by contact, the attractive power thus developed continuing, in soft iron, the contact lasts, whereas, in hard iron, and more especially in steel, it separation from the natural magnet. A bar of steel rubbed lengthw constant direction, with the pole of a natural magnet, becomes itself a of attracting iron, and imparting its power in like manner to other bar

Another mode of imparting magnetism to iron or steel is by the acti current or discharge, as already described in the article Electricity (ii bar, placed within a helix of wire through which an electric current is a permanent magnet. Lastly, as we shall presently explain more par of iron or steel may be rendered magnetic by placing it in a certain po to the earth.

The properties of magnets are the same in whatever manner their developed.

There are only two other metals, viz. nickel and cobalt, in which the can be conspicuously developed by the means above mentioned: in ni siderable, but much less powerful than in iron; and in cobalt, still l bodies are, indeed, more or less susceptible of magnetic influence, but effects only when subjected to very powerful electric or magnetic forces cases, the mode of manifestation is very different from that which is ex See Diamagnetism (p. 770).

Distribution of Magnetic Power.—In a magnetised steel bar, as in the the attractive power is not uniformly distributed, but is more or less certain points called poles, situated at or near the ends of the bar, w nishes with greater or less rapidity and regularity towards an interm rather line, called the median line, generally in the middle of the bar shown by rolling the bar in iron filings, which then attach themselves in the ends, leaving the middle bare, as in *fig.* 716. If the two poles have

Figs. 716.

Fig. 717.

AGNETISM, TERRESTRIAL.)

NETIC ATTRACTION AND REPULSION.

iron is attracted indifferently by either pole of a magnet,
served, that the attraction is mutual, so that, whichever of
ve towards the other; and if both are movable, they will
velocities which are inversely as their masses. Hence, if a
or steel be presented to either pole of a magnetic needle,
ds it. But, when a magnetised bar is presented to the
north pole of the one attracts the south pole of the other,
south pole attracts a north pole, but repels a south. The
traction and repulsion is then exactly similar to that of
sion (ii. 376), viz. *Similar magnetic poles repel, dissimilar*
Hence, to determine whether any piece of iron or steel is
icient to present the several parts of its surface to a deli-
needle: if every part attracts the needle, the piece of iron
rity; if, on the other hand, some parts attract, while others
e, the iron is shown to be magnetic, and the number and
determined.
epulsion are not prevented by the interposition of any sub-
of magnetism. If a magnetic needle be deflected from its
a piece of iron, or another magnet, near it, and allowed to

settle itself in its position of equilibrium, that position will not
interposition of a screen of paper, wood, glass, copper, &c.; but, i
interposed, the needle will immediately take up a new position, th
magnetic forces being altered by the interposition of the iron.

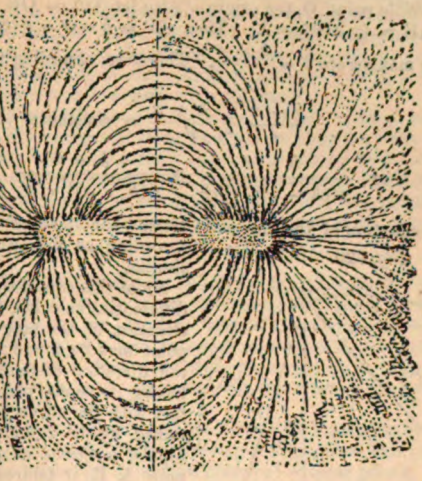
*The force of magnetic attraction and repulsion varies inversel
the distance between the poles or centres of action.*—By the term
understand the point of application of all the forces exerted by o
on any point of the other. It is evident, then, that the poles mu
according to the distance between the magnets; but unless the ma
together, the distance between their poles will not differ sensib
exists when the magnets are placed so far apart that all the ac
regarded as parallel. The poles, understood in this sense, do not of
the points of strongest attraction, which are generally at the ends
they are nearer to those points in proportion as the magnetic po
rapidly from the ends towards the middle.

This law of magnetic action may be demonstrated in three ways:
Balance.—The construction of the magnetic torsion-balance is sim
described (ii. 380) for the measurement of the electric forces, the s
replaced by a magnetic needle, and the shellac stem by a bar-mag
experimenting to determine the law of magnetic action with re
exactly similar to that described at page 381, vol. ii., for meas
electric attraction and repulsion.

2. *By the Method of Oscillations.*—Suppose a magnetic needle t
bar-magnet, with its centre on the prolongation of the axis of that m
place itself in the direction of that axis, and if disturbed from
oscillate backwards and forwards, and ultimately settle in its origin
brium. Now the oscillations of the needle thus vibrating under the i
attraction, are regulated by the same laws as those of a pendulum
influence of gravity, that is to say, *the squares of the times of oscilla
the attracting forces.* Supposing then the power of the magnet an
constant during the experiment, the diminution of the attractiv
distances may be measured by counting the number of oscillations w
forms in a given time at different distances. It is necessary to observ
the oscillations of the needle are determined by the magnetic force
as by that of the magnet, the terrestrial force must be either compen

To simplify the calculations as much as possible, the experiment
with an *astatic needle*, that is to say, a system composed of two
equal power, joined together parallel to one another, but with the
directions, by a small piece of straw or copper wire passing throu
gravity (ii. 443); such a combination will evidently place itself
positions relatively to the magnetic meridian, because the magneti
acts on the two needles composing it with equal force but in opposi
let one of the poles of such a needle be brought near the contrary p
of such a length that the action of its farther pole may be left ou
distance between the poles of the magnet and needle is then t
needle made to vibrate, and the number of its oscillations perform
counted. The needle is then removed to a greater distance and
repeated. If then m and m' are the magnetic forces at the distance
corresponding numbers of oscillations in the same time; we have
Now experiment shows that the quantities n, n' d, d' are relat
$n : n' = d' : d$, that is to say, the number of oscillations in a given
as the distances; consequently

$$m : m' = d'^3 : d^3.$$



The same result may be attained by the use of a needle not ren
N be the number of oscillations which it makes in a given time un
the earth's magnetism alone; n the number performed in the same
influence of the terrestrial force and that of a magnet placed at a ce
the needle in the magnetic meridian; and n' the number perfor
when the magnet is removed to a greater distance. If then the ma
earth, and of the magnet at the two distances mentioned, be de
respectively, we shall have

$$N^2 : n^2 = F : m + F$$
$$\text{and } N^2 : n'^2 = F : m' + F$$
$$\text{therefore } n^2 - N^2 : N^2 = m : F$$
$$\text{and } n'^2 - N^2 : N^2 = m' : F$$
$$\text{and finally } m : m' = n^2 - N^2 : n'^2 - N^2.$$

Magnetic Curves.—Place a bar-magnet under a sheet of stiff
fine iron filings on the paper through a gauze sieve. These
elves round the magnet in peculiar curves (*fig.* 719), radiating

Fig. 719.

oles. Now these curves are clearly the graphic expression of
action and repulsion with regard to distance: for each of the
e of the magnet becomes itself a small magnet, the poles of
a position determined by the resultant of the forces exerted
les of the magnet; and this position of equilibrium varies
of the filing from the two poles respectively. In fact, a small
n any part of the paper, will settle itself in the direction of a
ssing through that point. If placed on any point of the
f the magnet, it will take up a position parallel to that axis
nsecutively with those of the bar-magnet; at any point on the
entre of the magnet at right angles to its axis—every point
nt from the two poles—the needle will place itself parallel to
les in the contrary direction; and in any intermediate position,
f obliquely to the magnet, its inclination increasing with the
from the two poles.

neration of the magnetic curves—or, what comes to the same
tion—can be determined, the law of force with regard to
from it. The curves may be obtained in a state convenient
ing them over a plate of glass in the manner above described,
t of paper covered with gum or starch paste. In this manner
the paper, and the curves may be measured.

ts of the curves formed by the joint action of two magnetic
imilar, on iron filings or infinitely small magnets, Roget has
law: *The difference of the cosines of the angles formed with the
ning the two poles) by lines drawn from these two poles to any
is a constant quantity, the two angles being taken on the same*

n instrument for tracing the curves by continued motion,
and has also given the following method for describing them

centre, and with any radii whatever, describe two circles;
eets both these circles; divide the whole length into any
d project each point of division perpendicularly on the two
indefinitely prolonged be then drawn through the centre of

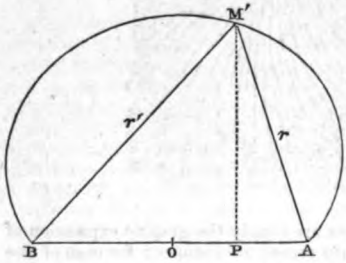
nging to the curves.

are of contrary name, the curves are said to be *converging*
vilinear diagonals in the direction of the magnetic axis of the

Digitized by Google

quadrilaterals formed by the intersection of the rays. If on the other hand th poles are of the same name, the curves are said to be *divergent*, their direction that of the curvilinear diagonals perpendicular to the former.



Now let A, B (*fig.* 720) be the two magnetic poles, M a point of the curve co-ordinates, referred to two rectangular axes, are x and y. Let AB be the of x, and its middle point, O, the origin. Also let $OA = OB = h$; $AM = r$; r'; angle $MAB = i$; $MBA = i$. Then $AP = h - x = r \cos i$; therefore co $\frac{h-x}{r}$; in like manner $\cos i' = \frac{h+x}{r'}$. Therefore, according to Roget's law,

$$\frac{h-x}{r} \pm \frac{h+x}{r'} = \text{constant};$$

$$\text{or } \frac{h-x}{\sqrt{(h-x)^2+y^2}} \pm \frac{h+x}{\sqrt{(h+x)^2+y^2}} = \text{constant}.$$

This is the equation of the magnetic curves, the upper or lower sign being according as the two poles are opposi similar.

Fig. 720.

From this equation, by the processes differential calculus, the expression of t clination of the tangent to the curve point may be found; and as this tang the direction assumed by a magnetic having its centre placed over the point o tact with the curve, which direction is mined by the resultant of the attractiv repulsive actions exerted upon it by th poles A, B, it follows that the value o inclination, properly expressed in ter the distance of the point of contact fro two poles, will give the law of variati the intensity according to the distance. When these calculations are ma is found, in accordance with the results of the other modes of measurement described, that the intensity of the force of magnetic attraction and repulsion inversely as the square of the distance. (See De La Rive, *Traité de l'Electricité*, t note D, p. 592.)

Comparison of the Power of different Magnets. Distribution of Magnetism

The old method of comparing the power of magnets, or of different parts of the magnet, consisted in ascertaining the weights which they were capable of suppo This method, however, can give only a rough approximation to the truth, inasm the weight which a magnet can support depends in great measure on the man which the weight is applied, and on the rate at which it is increased. When the with which a magnet is loaded is very gradually increased, it is found to be capa supporting a much larger weight than could be supported by it if applied all at

Much more exact results are obtained with the torsion balance and by the met oscillations, both of which methods have been applied to this purpose by Coulom

To compare the force of two or more magnets by the torsion balance, these m are introduced successively through the hole m (*fig.* 373; ii. 380) and the nee the balance is kept at a constant angular distance by twisting the thread through ent angles, which are to one another as the forces to be overcome. When the m of oscillations is employed, the magnets are placed successively at a constant di from the needle, this distance being so great that they cannot alter the distribut its magnetic power.

Magnetic Moments.—Another mode of comparing the power of magnets is to each of them successively in a small stirrup suspended from the thread of the to balance, so that the magnet may remain in the magnetic meridian when the thread twisted. The thread has then to be twisted through different degrees, so as to for each magnet the same angle of deviation from the magnetic meridian. The of torsion thus found represent what Coulomb calls the magnetic moments several bars. It is evident that the magnetic moment depends both on the ma intensity of the bar, and on the distance of its poles from the axis of suspension.

Distribution of Magnetism.—To measure the relative attractive or repulsive exerted by the different parts of a bar-magnet, Coulomb introduced a vertical w rule into the glass case of the torsion-balance, in such a position that it touch needle of the balance which rested in the magnetic meridian when the threa

this rule was a vertical groove in which the magnet to be
p and down, so as to bring the several parts of its length
needle of the same name as the half of the bar which was
e was thereby repelled; and to bring it back to its original
be twisted through a certain angle, which measured the
ie bar was then shifted in the groove, so as to bring another
pole of the needle, and a similar experiment was made.
y close to the needle, it is only the points very nearly on a
can exert any sensible influence over it, those which are
e or below, acting too obliquely.
f oscillations to the same purpose, a small needle, magne-
its magnetic state may not be altered by the action of the
r different parts of the bar. Denoting by m, m' the magnetic
oints, and by N, n, n' the number of oscillations made in
ience of the earth alone, and under this influence added to
e bar under consideration, we find, as on page 758,

$$m : m' = n^2 - N^2 : n'^2 - N^2.$$

ives directly the relative magnetic intensity of any part of
emities, for which the intensities found by direct experi-
der to give the true force at these points, as compared with
erved at these extreme points would evidently be double
o be, if the magnet were prolonged, so as to present, beyond
equal magnetic force with those which are within them, as
art of the bar.
hese methods may be represented graphically by erecting,
rizontal line representing a magnetised bar, perpendiculars
al to the intensities observed at these points. The ends of

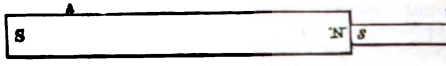
kable that for all rectangular or cylindrical bars whose
ds 20 centimetres (or 8 inches) the form of this curve, that
e distribution of the magnetism, is the same, excepting that
the middle, where the magnetic power is little or nothing,
eater or smaller space according to the length of the bar.
that is to say, the points of application of the resultants of
exerted on each half of the magnet by an infinitely small
gnetic element, placed at such a distance that all the lines
be regarded as parallel, correspond with the centres of
ie surfaces enclosed by the curves of intensity. Hence
iets of equal force and longer than 20 centimetres, the
uated at the same distance from the extremities: this
ording to Coulomb's calculation, is about 4 centimetres
ches). In shorter bars they are situated at about two
distance from the centre to the ends.
ding results apply only to magnets whose length is very
portion to their transverse dimensions, and in which the

at is, prismatic or cylindrical, and the magnetisation likewise
needles, the poles are much farther from the extremities.

Magnetic Induction.



oned that a piece of iron or steel placed in contact with a
tural or artificial, becomes itself a magnet. This action
with diminished intensity, at a distance, and is not pre-
of non-magnetic bodies. This effect is called magnetic
cording to which it takes place is precisely analogous to that
), viz. that *The extremity of the iron or steel nearest to the*
mes a pole of contrary name, and the farther extremity a
he inducing pole. Thus, suppose a bar of soft iron to be
orth pole of a magnet; on presenting a magnetic needle to
edle will turn its south pole to the bar, showing that that

Digitized by Google

end has become a north pole. If the bar be detached and the ind moved, the polarity of the bar is immediately destroyed, and the n normal position; and if the south pole of the magnet be now plac or near to the end of the bar, the needle will turn round and presen the farther extremity. The polarity of the end of the bar which the inducing magnet, cannot easily be tested in a similar manner, contrary action of the inducing pole; but if a short steel bar be soft iron, and left in contact with the magnet for a few seconds, it v rated, exhibit two poles, that which has been in contact with the p magnet being a pole of contrary name.

Moreover, the iron or steel thus rendered magnetic by induction wi similar manner on any other piece of iron or steel in its neighbo polarity in it, if previously unmagnetised, and altering the distribu of its polarity if previously magnetised. Consequently, just as th of a charged body is intensified by developing electricity in a neigh (ii. 385) so likewise may the polarity of a magnetic bar be strengt magnetism in a neighbouring piece of iron. Thus, suppose a bar of placed in contact with the north pole of a steel magnet, A, in the n in *fig.* 722, B will then become a magnet with its poles disposed si

Fig. 722.

A, and will act upon A, just as if B were the original magnet, and A iron. The original polarity of A will therefore be strengthened; and that a steel magnet is rendered more powerful and capable of su weight, by leaving pieces of soft iron in contact with its poles.

It will be easily understood, from the preceding exp'anations, th unmagnetised iron by the magnet is not an isolated phenomenon, l cular case of the general law of the attraction between similar ma is also easily shown by experiment. Suspend a piece of iron, a ke the north pole of a bar magnet; then bring the north pole of a secon with the first; the key will be held with greater force than befor magnets polarise it in the same way. Now turn the second magn its south pole in contact with the north pole of the first; the ke drop off, because the second magnet induces in it a polarity con first, and reduces it to the condition of unmagnetised iron.

The case is, however, different if the two magnets act at oppos magnetised iron. Thus, let two magnetic poles P, P′, (*fig.* 723) be with the two ends of a bar of soft iron B, not more than two or th the poles P, P′, are similar, the iron will not be held up by them, b

Fig. 723.

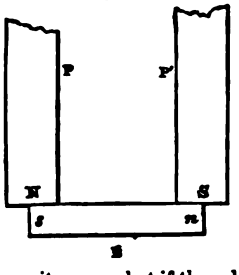


Fig. 724.

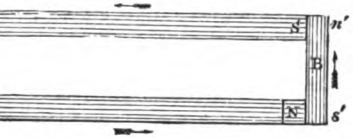

polarise it in opposite ways; but if the poles P, P′ are dissimilar, the will conspire, and the piece of iron will be held up with greater for by either of them alone. Hence also a magnet bent in the form o 724) will hold a piece of iron placed across its poles, with great magnet of the same size and intrinsic magnetic force; and by u such horse-shoe magnets with their similar poles together, great pow

Another fact tending to show that the attraction of iron by a ma ceded by magnetisation of the iron is, that very hard steel, which a slowly is scarcely attracted by the magnet.

cular Constitution of Magnets.

omena hitherto considered are consistent with the sup-
larity resides in one half of the magnet, and the south
kind of polarity gradually increasing in intensity from
ds. But there are certain effects which show that mag-
resides in molecules, not in masses. Take a steel wire
break it in the middle. It will be found that each half
ng a north and a south pole, with a median line between
be again divided in the middle, four complete magnets
ving a north and a south pole, and so on, to whatever
carried. This result is easily intelligible, if we suppose the
ection of molecules, each having a north and a south pole,
inting the same way. It is easy to see that, in such a row of
e opposite polarities towards the middle of the series will

Fig. 726.

only those of the two extremities will be perceptible; but
ed at any point, each half will exhibit polarity similar to
uch a series of polarised particles really acts like an ordi-
by partly filling a glass tube with steel filings, and passing
t five or six times along the outside of it in one constant
shake the tube. The individual filings will thus be mag-
mn, if presented to a magnetic needle, will attract and repel
ary bar magnet, exhibiting a north pole at one end, a south
larity in the middle; but on shaking the tube, or turning
hem in again, so as to destroy the regularity of the arrange-
y will disappear.
to observe that, in a single row of particles, such as that in
ual magnetic polarity, the resultant polarity would be exhi-
remities. Now, this is not what is actually observed in
e must be attributed to the lateral actions of the particles
ng the magnet, one on the other.

rocesses of Magnetisation.

d of the molecular constitution of magnets, it is clear that
must consist in polarising each separate molecule of which
, when a bar of soft iron is placed in contact with a mag-
icles become polarised by the direct influence of that pole,
thus the polarisation is rapidly developed all along the bar.
er a certain resistance, called the coercive force, to the
les, so that the development of magnetism in them, espe-
proportion to the hardness of the temper. Thus, when a
in contact with the north pole of a magnet, the nearer
mes a south pole, but the farther end shows no polarity at
wever, formed at a short distance from the south, and near
ole, just as if the bar were divided at that point, and the
acted like a separate magnet on the portion beyond. These

Digitized by Google

poles gradually advance along the bar, a feeble south pole appearing
the farther end, succeeded, after a while—if the bar is not too long—
the bar then appearing regularly magnetised. If, however, the bar is
made of very hard steel, it never attains this regular magnetisation,
series of alternate or *consecutive* poles, which never reach its farther e
coercive force may, however, be more or less overcome, and regular
facilitated, by striking the bar with a piece of metal, so as to make it
its particles into vibration.

It is obvious that the polarisation of the whole series of particles con
will be accelerated by laying it between two bar magnets, with their
facing one another, or across the poles of a horse-shoe-magnet, the mag
taking place in two directions at once, and both tending to the same re

Another process more generally adopted, consists in passing the po
from one end to the other of the piece of steel to be magnetised, repeat
several times and always in the same direction. Each particle of th
brought successively under the influence of the magnet, and it is
magnetic power of the bar increases with the number of strokes up to
after which no further increase takes place. The polarity imparted to
the magnetic pole approaches it, is reversed when the pole passes ove
polarity finally imparted to the bar is that which corresponds to the las
inducing magnetic pole. If, for example, the steel bar be rubbed with t
a magnet, the end first touched will be a north, and the other end, by w
leaves the bar, will be a south pole. It is not very easy to understand
by repeating the friction, inasmuch as the polarity imparted by each str
at the commencement of the next. Possibly the coercive force of th
come by the disturbance consequent on the continued reversal of the po
the same manner as it is by vibration.

Greater power may be obtained by a combination of the two methods
namely, by laying the bar to be magnetised between the opposite poles
or those of a horse-shoe-magnet, then, taking two other bar magnets, on
bring down their opposite poles on the middle of the bar to be magnetis
them at an inclination of 25° or 30°, draw them outwards, with a
towards the extremities of the bar. Ten or twelve strokes given in th
always in the same direction, will give to the bar, if not very large, as
power as it is capable of retaining. It is of course necessary that t
movable magnet which touches the bar, should be of the same name
fixed magnetic pole towards which it is made to move. This metho
Duhamel, and called the *method of single touch*, is the best for magn
needles, and bars of no great length and thickness, in which regular
magnetism is desired rather than great attractive power; but for ma
thick bars, especially when it is desired to give them their full power
method of Æpinus, called the *double touch*, is to be preferred. The bar
two powerful magnets as in the preceding method, and likewise rubbed wi
poles of two magnets; but instead of drawing these poles from the mid
opposite ends of the bar, they are tied together, with a piece of cork o
them to keep them at a certain distance apart, and made to travel toge
bar, first one way and then the other, beginning and leaving off in the m
shoe-magnet may be conveniently used instead of two bar-magnets tied
this method it is likewise easy to magnetise two steel bars together, nan
them parallel to one another, with soft iron keepers across their extremitie
and passing the two magnetic poles several times round the rectangl
beginning in the middle of one of the bars, and leaving off at the same
as indeed in all methods of magnetising, the bars, after having been r
number of times on one side, should be turned round and rubbed in th
on the other.

In both these methods, when two movable magnets are employed, the
any particle acquires while outside the magnetic poles, is reversed
motion it is brought between them. Now the advantage of the doubl
consists in this, that the two poles of the movable magnet or magnets a
only a small distance, so that the sum of their actions on a particle betwee
as great, and the difference of their actions on an outside particle as sm
This very circumstance, however, by developing powerful magnetism
particular part of the bar, creates a tendency to the formation of consecu
the steel is very hard. Hence, as already observed, the single touch me
adopted where regularity of magnetisation is the main object in view.

Magnetisation by the Electric Current.—Very great magnetic power m
in soft iron by placing it within a long coil of wire through which an

Digitized by Google

ars may be magnetised in the same way, but the magnetism
ut feeble, apparently because there is a want of vibratory
ie coercive force. The magnetisation may indeed be
es, by striking the bar so as to make it ring while it is
urrent; but the best mode of magnetising steel bars by the
the bar through a short movable coil of wire, then fix it
ctro-magnets, the coils of which are connected with the
one continuous circuit, and, having made the connection
e movable coil backwards and forwards along the whole
it at the same time against its surface, so as to excite a
icles. In this way very powerful and regular magnetisation
Traité de Physique, iii. 608). It is easy to see, however,
sation requires rather complex apparatus, especially as, to
sm in soft iron requires a very long coil of wire passing
, and consequently a powerful battery of several cells to
he circuit. In most cases, therefore, the simpler methods of
and double touch are found more convenient.

rial Induction.—If a bar of soft iron, destitute of magnetism
e held in the line of the magnetic dip, or in the vertical
titudes does not differ greatly from it, its lower extremity
red north, and the upper, south polarity. On reversing the
o reversed, the lower extremity being still a north pole.
nductive action of the earth, the northern hemisphere of
rved, like the south pole of an ordinary magnet.

el held in a similar position, does not immediately exhibit
striking it several times with a key or a hammer, it be-
ised with its north pole downwards. In this way, perma-
ined without the use of other magnets or of the electric
el may be greatly augmented by resting it on a bar of iron
oth. Scores by obtained powerful magnets by the following
was placed vertically and struck, and having thus acquired
tic power, it was placed successively on each of two steel

diameter. 3. The time of oscillation of a bar having a rectangular breadth is *l*, thickness *e*, and length 2L, is given by the formula:

$$t = me\sqrt{l} + n\,L,$$

in which *m* and *n* are constants, depending on the nature and hardness

With regard to form, Coulomb found that thin lozenge-shaped bars *directive force* than rectangular needles of the same weight, thickness, a

Influence of Hardening and Tempering.—Coulomb, having magneti to saturation, after hardening it to different degrees, and testing it method of oscillations, obtained the following numbers:—

Temperature of hardening	875°	975°	1075°
Time of 10 oscillations	93″	78″	64″

Steel does not undergo any sensible modification of structure wh temperatures below 870°, and accordingly the magnetic results are t degrees of hardening below this limit; but when hardened at about 11 capable of acquiring double the magnetic force which it retains when ha temperatures: for the time occupied by the ten oscillations being 63″ ins magnetic forces are inversely as the squares of these numbers, that is as

A steel bar hardened at a cherry-red heat, and then magnetised aft tempered at different degrees, gave the following results:

Tempering heat	15°	267°	512°
Time of 10 oscillations . . .	63″	64·5″	70″

Hence it appears that the magnetic force is less in proportion as the ste pered, the coercive force in fact diminishing with the hardness.

Very different results were obtained with thin and very elongated lam By magnetising them at different degrees of hardness, Coulomb found dened at a white heat, they did not retain a higher degree of magne after having been completely tempered. In proportion as the hardness by tempering, the magnetisation became stronger, down to the temperi a dull red heat. On tempering them still more, the directive force w capable of receiving continually diminished. Biot explains this anomal tion of two consecutive poles in very elongated and strongly hardened ne of the needle thus possessing two poles of contrary name, whereby the d greatly lessened. But as the hardness is diminished, the poles neare approach continually nearer to it, and finally disappear altogether.

Compass needles are usually tempered at the blue, that is to say, at In this state, the coercive force, though not at its maximum, is still very steel is less fragile than when more hardened, and less liable to acquire co

Nobili (Bibl. Univ. lvi. 82) has endeavoured to explain the influen on magnetisation by the inequality of density of the different parts of the He found that when a bundle of thin steel wires (about 50) was very st tised, and the wires separated a short time afterwards, each of them ap magnetised in the same direction; but when the bundle was made up ag a few hours afterwards, several of the wires were found to be unmagnet had had their polarity reversed. Similar results had previously bee Coulomb. It appears then that, in a system of parallel rows of magnetised which are most strongly polarised destroy or reverse the polarity of the and determine the polarity of the whole, and if the original polarity of all equal, the magnetic power of the entire system would probably soon be a magnetised bar may be regarded as made up of concentric layers of pola and if the external shell is rendered denser than the interior by harde larger number of magnetic elements are there included within a given ternal shell will receive a higher degree of polarity than the external accordingly will neutralise their action and determine the polarity of the For the same reason soft iron which has been hammered or wire-drawn power of retaining a certain portion of magnetism. According to this cive or retaining power does not depend upon any peculiarity in the pl mical constitution of steel, but is entirely due to the different densities ficial portions of its mass. This is in accordance with the fact that capable of retaining a proportionally greater power than large ones, thei greater in proportion to their volume. It is also supported by the fol ment made by Nobili. Two cylinders were constructed of the same kin of equal length and diameter, but one solid, weighing 28 grms. the weighing 16 grms. They were then hardened to the same degree, and b netised to saturation. When placed at equal distances from a comp solid cylinder deflected it 9½°, the hollow cylinder 19°. The great diffe

Wertheim has made numerous experiments on the relations betw and torsion, by a method similar to that of Becquerel, using however of iron enveloped by two helices, one formed of thick wire to receive th magnetises the bar, the other of a long thin wire to receive the induc convey them to a galvanometer. The helices are placed near the ends occupy but a small portion of its length. Having first shown that always possesses a certain amount of coercive power, and therefore a certain amount of the magnetic polarity once induced in it, Wertheim following results:—1. Torsion and detorsion do not by themselves de netism in iron: for on placing the bar at right angles to the magnet twisting it, no induced current is developed.—2. If the bar is placed meridian, or subjected to the action of a magnet placed on the continu or to the action of the electric current, the magnetising action of either is accelerated both by torsion and by detorsion; but when once equilibrium is established, torsion weakens the total magnetisation restores it to its former amount: hence the maximum of magnetisation the state of *mechanical equilibrium*.—3. If the bar is withdrawn from t magnetising agent, repeated torsion and detorsion quickly destroys the porary magnetisation, but continues to act indefinitely on the permanen which is diminished by torsion and restored by detorsion.—4. When t given condition of magnetic equilibrium, all the effects of torsion are the angles of torsion; but the magnitude of these effects appears to de upon the permanent magnetisation, than on the temporary magnetisati the external cause.—5. The form of the section of the bar does not any influence, but the deflections increase with its area and with the magnetisation.—6. The order of the effects produced is the same for a the only difference being in the absolute intensities of those effects. T requires the greatest number of torsions and detorsions, to bring it to magnetic equilibrium, indicated by the equality of the opposite indu 7. Steel also, the more it is hardened, requires a greater number o detorsions to bring it to a state of magnetic equilibrium; but equilibrium is established, it cannot, according to Wertheim, be mod and detorsion alone, as is the case with iron. Matteucci, on the oth obtained feeble currents in this case, these currents being weaker as the hardened. Hard iron exhibits an anomaly which has not been explaine tion produced in it by torsion being greater immediately after the inte magnetising current than during its passage. In this case, the dimi take place till after some time.

When the bar is in a state of temporary or permanent torsion be tion, similar results are obtained; that is to say, the magnetic maximu not with the initial state of torsion, but with that which exists i mechanical equilibrium; so that the magnetism increases when the b the direction which diminishes the primitive torsion, and diminishes wi torsion is re-established. But if the initial permanent torsion is pro bar is under the action of the magnetising current, a *rotation of th* observed; that is to say, the maximum is displaced, and in the direction the angle of rotation being greater as the iron is harder, and the per greater. This angle is always less than half the temporary torsion wh takes place during the production of a permanent torsion.

For further details on this subject, and on the reciprocal influence of torsion, see Wiedemann (*Galvanismus und Electro-magnetismus*, ii.

Traction and Flection.—According to Matteucci, a sudden elong by tension in a wire of iron or steel, while subjected to the magnetisi electric current, produces an *increase* in the magnetic force, and a sud diminishes it. These results have been confirmed by Wertheim, who that *flection* and *deflection* act in the same manner as torsion and detors effects are due to the displacements of the molecules produced by these whereby they are enabled to arrange themselves, either in the position for magnetisation, or the contrary.

Wertheim finds, in the increase of the magnetic capacity of iron by planation of the well-known fact, that a magnet while loaded becom stronger, but returns to its primitive state as soon as the weight is rem attributes the great irregularities of the compass in large iron ships to flections of the iron which take place during the voyage, these flect changes in the magnetisation of the iron, of which the *compensato* unable to take account. These phenomena are the converse of tho Joule (Phil. Mag. xxx. 76 and 225), who found that an iron bar increases

tism compared with Electricity.

netic induction, above described, are analogous in almost
f static electric induction; but there is one essential dif-
there is no such thing as magnetic discharge. In the
we know that, when the opposite polarities of the neigh-
certain degree of intensity, discharge takes place between
ark; and the distribution of the electric forces, after this
same as before, the one body appearing to have lost a
and the other to have gained it (ii. 385). But in magnetic
ind is observed. Whatever may be the power of a magnet,
ece of soft iron may be polarised by contact with it, the iron
magnet; but as soon as the contact is broken, the soft iron
teel magnet is found to have lost nothing, but rather to have
. Neither does hard iron or steel, though it remains mag-
ake any power from the original magnet, its retention of
gous, not to the condition of a body which has been electri-
non-conducting body like sealing-wax, which has been elec-
and then removed from the neighbourhood of the inducing body.
netism are not then precisely analogous to those of static
; the exact parallelism which exists between the two up to a
ready explained under ELECTRICITY (ii. 447), the laws of
pulsion are exactly similar to those of the mutual action of
lices of copper wire, through which electric currents are
one another exactly like magnets, and, accordingly, all the
traction and repulsion may be accounted for, if we assume
n aggregate of particles having electric currents constantly
one direction. This theory has been sufficiently developed
nd we need not dwell upon it further.

teel is rendered magnetic by the action of an electric current
gles to its length, we must suppose, if this theory be true,
the power of inducing in magnetic bodies a system of electric
ion as itself; moreover, that these currents, once established,
as long as the original current continues to act, and, in the
has ceased. Now, this is not what is observed to take place
rrents on conducting bodies in general. We know that when
a closed circuit is placed near another wire conveying an
, at the instant when it begins to flow, induces, in the first
direction to itself, this current, however, being merely in-
ed current being perceptible so long as the inducing current
iform strength; and, finally, that when the original current
it is broken), another momentary current passes through the
direction as the inducing current. These effects of electro-
idently totally different from those which must be supposed
according to Ampère's theory; and we must, therefore, sup-
have a peculiar molecular constitution, which enables an
ar them to excite continuous currents round their particles in
wn; or rather, perhaps, that these currents pre-exist in all
re the development of magnetic polarity, but are disposed
hat they neutralise one another; and that magnetisation,
nt, or by another magnet, is the process by which these mole-
move in one direction (ii. 448).

molecules of magnetic bodies, such as iron and steel, are en-
ed currents of electricity, which, before the development of
e indiscriminately in all planes, but, in a magnetised bar,
that, on the whole, the prevailing direction of rotation is in
of the hands of a watch conceived as situated at the centre
wards the south pole and its back towards the north pole,
ar to the line joining the two poles: this hypothesis accounts
facts connected with magnetisation, and receives from some
nation. According to this view, magnetisation consists in
piece of iron such an arrangement that the prevailing direc-
nts shall be that indicated above. Coercive force is, on the
the motion of the particles, which requires to be overcome
etisation or demagnetisation; and the saturated state of a

Digitized by Google

magnet is when the greatest possible number of molecular currents circulate
same direction, with their axes parallel to that of the magnet.

That magnetisation is really attended by molecular motion is proved by the er
of musical sounds by a piece of soft iron which is suddenly magnetised or der
tised, when it is so supported that the greater part of its mass is free to vibrate.
magnetic effects developed by torsion likewise show the intimate connection b
molecular motion and magnetisation. This view also enables us to see why the c
force of steel is increased by hardening; for the hardness of steel is nothing mo
the result of the great resistance which its molecules oppose to mutual motion
difference between the molecules of soft iron and those of steel with respect t
netisation, may be regarded as analogous to that presented by a very finely
magnetic needle and one that is coarsely hung, when a magnet is brought near
The finely hung needle is immediately and completely turned from its normal p

the coarsely suspended needle, however, is at first much less affected by the m
and does not turn to the full extent until the friction of its point of support is ov
by a gentle tap or shake, and, similarly, when the disturbing magnet is taken away,
not return completely to its first position without the same aid. This comparisc
serve to explain the influence of a blow or vibration in facilitating the magnetisa
an unmagnetised steel bar, and in weakening the force of a saturated steel mag

Universality of Magnetic Action—Diamagnetism.

Magnetism was for a long time regarded as peculiar to a small number of bodies, n
iron, nickel, cobalt, and certain of their compounds; but later researches have shown
bodies are more or less susceptible of magnetic influence, though they are not all a
in the same way. The question of the universality of magnetism was raised as e
the beginning of the eighteenth century. Muschenbroek and Nollet found
large number of bodies in the state of powder, the ashes of plants, and small fra
of organic substances, were attracted by the magnet; but they attributed the re
the presence of small quantities of iron in the substances examined. The subje
also investigated by Lehmann and Cavallo; and Brugmanns, in 1778, ob
that bismuth is *repelled* by the poles of powerful magnets,—a remarkable dis
which did not receive at the time the attention it deserved. Coulomb, in
found that fine needles of gold, silver, and other metals, also of glass, and of variou
table and animal substances, suspended by a thread of unspun silk between the o
poles of two powerful magnets, oscillated till they came to rest in a line betwe
poles; but he also showed that a very minute quantity of iron, not exceeding
intimately mixed with a needle of wax, was sufficient to produce this effect: he
considered it uncertain whether the effects observed were due to the action of th
nets on the various substances themselves, or on minute quantities of iron conta
them. After the discovery of electro-magnetism, Becquerel observed that
shellac, wood, and other substances, suspended by threads of unspun silk with
coil of a galvanometer, placed themselves with their axes *parallel* to the plane
coil, instead of at right angles to it, as an iron needle would: this effect was ex
in a remarkable manner by a paper tube filled with ferric oxide. Lebail
1828, found that a delicately suspended magnetic needle was repelled by bismu
antimony, thus confirming the important observation previously made by Brug
The same kind of repulsive action was subsequently observed by Saigey in
other substances.

But these facts, however important they may now appear, excited but little att
at the time of their discovery, inasmuch as they could not be referred to any
law; and the question of the universality of magnetism remained undecided
Faraday, in 1845, discovered that most transparent substances, when subjected
influence of powerful magnets, acquire the power of circular polarisation (p. 676
regarding this effect as resulting from the action of the magnet on the molec
the transparent body, he was led to undertake a series of researches which resu
the grand discovery, that all bodies whatever are subject to magnetic influenc
are not all affected by it in the same way, being divided, with respect to their ma
susceptibilities, into two great classes—the *Magnetic* and the *Diamagnetic*.
former class includes those bodies which exhibit the well-known phenomena o
nary magnetic attraction and repulsion—being *attracted*, when in their natural
by either pole of a magnet, and, when shaped into bars or rods, and suspended
two opposite magnetic poles, pointing *axially*—that is to say, in a straight line b
them. The bodies belonging to this class are mostly metallic (including oxides and

the axis, it is directed away from that line, just as if a gentle wind
it in that direction. When made to rise exactly in the axial line, i
two long tongues, directed at right angles to the axis. This effect i
ing with the large flame produced by setting fire to a ball of cott
These effects are evidently analogous to those just described with
are doubtless partly due to the solid carbonaceous particles in th
diamagnetic. In corroboration of this supposition, it is found
flames are the most strongly diamagnetic. (Faraday, Phil. Mag.
also Zantedeschi, xxxi. 421.)

Specific Magnetism. This term was introduced by E. Bec
the action exerted by a magnet on the unit of volume of a body pl
distance, as compared with that which is exerted on a certain subs
standard of comparison. Another mode of estimation is to comp
duced on a small magnetic needle, by a cube, equal to the unit of vo
unit of distance from the needle. The measurements are made e
balance, or by determining the weight required to keep the body i
of equilibrium while under the influence of the magnet.

By these methods, Plücker, representing the specific magneti
100,000, has found for native magnetic oxide the number 40,227, f
533, for brown hæmatite 71, which is the lowest number found f
pounds of iron, solid or liquid.

The following are the results obtained by Plücker for certain *dia*
at ordinary temperatures, and for equal weights referred to water a

Specific Diamagnetic Powers. (Plücker.)

polar line, it shortens. If the alcohol is saturated with protochl
bubble in the latter position splits into two, which move away from
ascertaining by trial the proportion of ferrous chloride, for which the b
no perceptible change of form, a solution will be obtained, having t
power as oxygen gas. By this method Matteucci found that oxyg
magnetic power as an alcoholic solution of ferrous chloride conta
grammes of iron in a cubic centimetre.

E. Becquerel has made numerous experiments for the purpose
magnetic power of oxygen as compared with water, and thence with
tube of glass filled with wax was suspended from a torsion apparatu
produced upon it by an electro-magnet in a vacuum, in oxygen and
pared. These actions, at the temperature of 12°, were, *in oxygen* u
0·76 met., $V_o = -0·2675$; in a vacuum, $V_v = -0·1145$; and
$+0·7033$. Hence $V_o - V_v = +0·1530$: $V_w - V_v = -$
magnetism of *oxygen*, compared with water *in vacuo*, is 0·1530 : 0
Hence, for equal volumes, the magnetic power of oxygen is nearly $\frac{1}{2}$
but of contrary sign. For *air* the same method gives the number 0
the magnetic power of oxygen multiplied by 0·21 is 0·392, it follows
power of the air is due to the oxygen contained in it. These resu
same as those obtained by Faraday (p. 773) and Matteucci; and Bec
confirmed them by Plücker's method. Lastly, he has shown that th
of oxygen is proportional to its pressure—a result probably true also

Taking the magnetic power of iron as the standard, and calling
find that, for *equal weights*, the magnetic power of oxygen is 377, a
Oxygen, *weight for weight*, has three times the magnetic power of
which is the most magnetic of all liquids. Hence a cubic metre of
act on a magnetic needle with the force of 54 centigrammes of iron,
of air with the force of 11 centigrammes of iron. The whole atmosphe
equal in magnetic power to a shell of iron covering the whole earth
0·1 millimetre. It is easy to conceive that such a magnetic envelo
constant agitation, is capable of disturbing the magnetic needle; a
power varies with its temperature (see below), the heating which
different hours of the day may contribute to produce the diurnal varia

Influence of Temperature on Magnetism and Diamagnetism.—The
the magnetic power of iron and steel has already been mentioned
formerly supposed that iron at a white heat becomes totally unsuscep
influence. Faraday has, however, shown that, though the susceptib
bodies properly so called is rapidly diminished by heat, it is
destroyed, but is still perceptible at the highest temperatures, provi
magnets of great power are employed to develope it. These result
firmed by Plücker, who has shown that the specific diamagnetism
solids and liquids diminish, for the most part, as their temperature i
there are some exceptions to the rule. Mercury, for example, exhib
diamagnetic power at 300°; neither do sulphur and stearin, even w
their melting points. Brunner has shown that water in the state of
has the same specific magnetism as in the liquid state.

According to Matteucci (Bibl. Univ. de Génève [Arch. des Sc
magnetism of iron increases up to a certain temperature, then decrea
diamagnetic power of bismuth diminishes between 0° and 212° C.—n
to the increase of temperature, and vanishes altogether at the melt
metallic bodies, on the contrary, such as sulphur and phosphorus,
diminution of diamagnetic power in consequence of change of state.

A globule of iron melted in a lime-spoon by the oxy-hydrogen
attracted by the magnet; but to exhibit the attraction, a very large el
required, charged with 30 Grove's cells. Matteucci estimates the m
melted iron at only 0·000015 of its power at common temperatures
surprising that iron at a white heat should have been found insensibl
power of ordinary magnets. Copper, standard gold, zinc, porcelain,
of charcoal, which according to Matteucci are magnetic at common tem
diamagnetic when heated. Platinum remains magnetic in the state
appearing scarcely to have suffered any diminution.

Heat appears also to diminish the magnetic power of gases: thus F
heated air is repelled by the magnet when surrounded by cold air (p. 77
however, concludes from his experiments on oxygen, that heat does

exhibited by compressed and crystallised bodies (p. 774)
ll some time ago (Phil. Mag. [4] ix. 205) objected
f diamagnetism as well as that of magnetism is in-
ereas, if the repulsion of a diamagnetic body were merely
ttraction exerted upon the particles of the surrounding
est in that direction in which the body is most compressed,
must increase the total amount of attraction exerted on
that direction, but cannot in any way affect that which is
medium. Williamson (Proc. Roy. Soc. vii. 306) has,
in considering this question, it is necessary also to take
rted on the magnetic medium (or *ether*) interposed between
c or diamagnetic body. When a cube of carbonate of iron
le particles being more magnetic than the medium which
n which the body is attracted is increased proportionally
es more magnetic by compression, we must conclude that
m from its interstices is more than supplied by the mag-
ts place. Carbonate of calcium, on the other hand, is less
of medium which its particles displace; and when these
together by pressure, the mass becomes more diamagnetic,
f the magnetic medium is thus replaced by the less mag-
ies, so long as they retain their original crystalline forms,
n in which the function of the ponderable particles predo-
that of the medium; so that in the iron-salt it is the
n-salt the feeblest magnetic direction of the crystal. On
roc. Roy. Soc. vii. 448) suggests that, in estimating the
et on the particles of a body and the magnetic medium
unt must be taken of the relative intensities of the action
different directions: and he endeavours to show, by a process
must refer to the paper above quoted, that, in two out of

dall's objection to the theory of a magnetic medium cannot be re
decisive.

On the whole, then, the phenomena exhibited by compressed and
do not quite decide the question whether diamagnetic repulsion is n
phenomenon, or whether it is due to the action of a specific force.
differential, can, as already observed, scarcely be doubted; but, on t
existence of diamagnetic polarity shows decidedly that the effect is
this cause: for if it were, every part of a diamagnetic body wou
either pole of a magnet.

It becomes necessary, therefore, to seek some further explanation o
diamagnetism; and the following theory has been proposed by Webe
We must suppose, in the first place, that each molecule of a body
polarity, by virtue of which, negative electricity tends to accumulate
c, of its surface (*fig.* 728), and positive electricity at the opposite
molecule is isolated and a good conductor, the two electricities wil
its surface, forming currents contrary to those which are continually b

e on the west and the Asiatic lines on the east—that is to
the Atlantic Ocean and the Old World—the declination
of the earth's surface it is to the east; and it diminishes
ı these lines. In London, at the present time (1864), the

Suppose a bar of unmagnetised steel to be suspended at its
ıd of unspun silk: it will come to rest in the horizontal
tised, it will not only place itself in the magnetic meridian,
position, the north pole in these latitudes pointing down-
inclination or dip of the needle is best observed by means
y its centre of gravity on a horizontal axis (*fig.* 730), so
ined to a vertical plane. A *dipping-needle* thus mounted
The horizontal circle serves to place the plane of the
gnetic meridian, and the vertical circle to measure the dip.

Digitized by Google

As the needle always tends to place itself in the magnetic meridian, it is c
if the vertical plane to which its movements are confined is placed at right
the magnetic meridian, the needle will stand
this being the only position in which it can pl
in the magnetic meridian. If this position be de
and marked on the horizontal circle, the verti
may be placed in the magnetic meridian by r
round 90° therefrom. The angle of inclinat
then be directly observed.

Fig. 730.

The dip, like the declination, is of different a
different localities. There are two points, one
hemisphere, at which the dipping-needle stand
vertical; these are called the magnetic pol
earth; and about midway between them is a li
the magnetic equator, or line of no dip,
it stands horizontally. The magnetic equator i
what sinuous line, not differing much from
circle inclined to the geographical equator at
of 12°, and cutting it in two points near the l
10° E. and 170° W., reckoned from the meridian
At all points between this line and the north
pole, the north pole of the needle is directed do
the contrary being the case in the other magne
sphere. The dip goes on increasing from the
equator towards each pole: in London at the present time it is 68° 15′, r
from the horizontal plane.

On comparing the positions assumed by the needle at different parts of th
surface, it is easily seen that they may be accounted for by regarding the earth
magnet, having its poles at the points where the dipping needle stands vertic
its median line coinciding with the magnetic equator. The northern t
magnetic pole, which corresponds with the south pole of an ordinary magnet, is
on the continent of North America, to the north-west of **Hudson's Bay**, and,
to the observations of Capt. J. C. Ross, made in 1830, in latitude 70° 5′ 17
longitude 96° 43′ W. from Greenwich (*Arago's Meteorological Essays, trans
Sabine*, p. 366). The position of the southern magnetic pole has been appro
fixed by the observations of the same navigator, in latitude 73° S. and longitu
The line of no declination passes through these two points, and the lines of eq
nation converge towards them. From observations made at different points in
and the south of Scotland, between March 1858, and October 1860, Sabine
68° 59′·2 as the dip at the mean epoch, 1st January, 1860, at a point whose
and longitude were the means of those of the stations included in the survey
latitude 52° 20′, longitude 1° 41′ W. from Greenwich. The minimum dip was
at St. Leonard's (latitude 50° 51′, longitude 0° 33′ E.), where it was 67° 44
the maximum 71° 29′·5, at Jordan Hill, near Glasgow (latitude 55° 52′,
4° 19′ W.), the direction of the *isoclinal lines*, or lines of equal dip, be
N. 71° 22′ E. to S. 71° 22′ W. (Rep. Brit. Assoc., 1861, p. 250).

That the earth really acts like a magnet, is further shown by the magneti
masses of iron placed in or near the line of the dip. In our latitude, where
of dip does not differ greatly from the vertical, bars of iron standing constant
vertical directions, such as railings, lightning-conductors, &c., become ma
with their north poles downwards, just as they would be if placed above t
pole of a steel magnet.

The magnetisation of the masses of iron in a ship by the earth's action,
considerable deviation of the compass-needle from its normal position; an
direction of the magnetisation thus induced is constantly changing as the shi
its latitude, it is evident that serious irregularities in the indications of the
may thence result: in short, there are several instances of shipwreck on reco
have been clearly traced to this cause. This source of irregularity may, ho
corrected by fixing a disc of iron, called a *compensator*, in such a position with
the compass, that its action shall be equal and opposite to that of the whol
iron in the ship: the needle will then be free to take up its normal position
influence of the earth's magnetism. It is, however, found better in practice
the compensator in such a position that it shall produce an action equal t
the iron in the ship, and *in the same direction*, so that, when placed in positi
double the deviation produced by the iron in the ship: the amount of this
will thus be ascertained, and may be allowed for. This great service to nav
the invention of Mr. Barlow, of Woolwich.

the native black oxide of iron is, doubtless, also due to the earth, and the very different powers exhibited by different y, in part at least, be attributed to the different position of he line of the magnetic dip.

Earth's Magnetic force.—The magnetic force of the nary magnet, is of different intensity in different parts. The rent places are measured by counting the number of oscilla- e by a magnetic needle: for these vibrations are subject to a pendulum, being isochronous when small, and the squares ions in a given time being proportional to the force which back to its position of equilibrium.

be made either with the dipping or the horizontal needle. s disturbed from its normal position of equilibrium, it is n by the whole force of the earth's magnetism: so that, if the l magnetic forces at any two places are devoted by F, F', and of oscillations made in a given time by n, n', we have, for the orces,

$$F : F' = n^2 : n'^2.$$

n the other hand, is urged back to its normal position by only force, which becomes less as the magnetic latitude is greater. ng on the needle in the line of the dip, may be resolved l, which is destroyed by the suspension, the other, f, horizon- effective in moving the needle; and if i be the dip at the horizontal force f is equal to $F \cos i$. Hence, for any two ntensities are F, F' the angles of dip i, i', and the numbers ve the relation,

$$\frac{n^2}{n'^2} = \frac{f}{f'} = \frac{F \cos i}{F' \cos i'}.$$

$$\frac{F}{F'} = \frac{n^2 \cos i'}{n'^2 \cos i'}.$$

or, $i = o$, $\cos i = 1$, and therefore $f = F$; at the magnetic fore $f = 0$: in fact, at these points, the horizontal needle ferently; and near the poles, the force which directs it is very ns cannot be depended upon. But, excepting in these high esults obtained with the horizontal needle are more trust- d with the dipping-needle, on account of errors affecting the ct horizontality in the axis, the friction on the supports, tal needle is easily suspended by a thread of unspun silk, fect freedom of motion. [For full details on the construc- observations on terrestrial magnetism, see Becquerel, *u Magnétisme*, Paris, 1840, tome vii. The atlas to that work f these instruments, and maps representing the directions and parallels on the surface of the globe. See also Daguin, ii. pp. 27, 55.]

increases with the latitude. Humboldt found a point of magnetic equator in Northern Peru. This value is gene- which the magnetic intensities at other parts of the globe are g table.

Manual of Scientific Inquiry; ed. 1859, p. 89.)

The mean amount of the total force in England, deduced by Sabine fr
survey already referred to (p. 780), for 1st January 1860, is 10·332
10·225, having been observed at St. Leonard's, and the maximum, 10·62
(lat. 56° 22; long. 3° 50′ W.). The direction of the *isodynamic l*
equal intensity, in England, at the above date, was from N. 57° 35′·7 E. t

The isodynamic lines differ considerably from the isoclinal lines, o
dip, but bear considerable resemblance to the isothermal lines; wh
probable that the magnetic intensity of the earth (like that of an o
is affected by heat. (For a chart of these lines, see Becquerel, *loc. cit.*)
Gauss, there are in each hemisphere two points of maximum magneti
ciding with the points of greatest cold, but not with the magnetic pole
the dip and declination of the needle.

Variations of the Magnetic Elements.

The declination, dip, and intensity at any point of the earth's surfac
continual variations, both regular and irregular; and the regular
two kinds: secular variations, of considerable amount, and exten
periods of time; and periodic variations, of small amount, and runni
phases at short intervals.

Variations of the Declination.—1. *Secular.* The earliest exact obse
magnetic declination were made at London in 1576, and at Paris in 158
in 1576, it was 11° 15′ to the east; from that time it diminished till 1
it was nothing, the needle then pointing due north and south; it then b
attaining its maximum of 24° 36′ in 1800. In 1831 it had diminishe
it is now (in 1864) 20° 45′ W. At Paris it was 11° 30′ E. in 1580, 0 in 1
maximum of 22° 34′ W. in 1814, and had diminished to 20° 25′ W. in
Cape of Good Hope, the declination in 1605 was 0° 30′ E., became n
1605 and 1609, then westerly, attaining its maximum of 25° 40′ W. a
all cases the declination given for each year is the mean of those obtain
and for each month, so as to eliminate the diurnal and annual variatio

2. *Annual.*—The declination of the needle is subject to small an
which were discovered by Cassini in 1780. At Paris and London, it i
the vernal equinox, diminishes from that time to the summer solstic
again during the nine following months. The annual variation does n
15′ to 18′. It is also different in amount at different epochs. At Lon
to 1820, it was reduced almost to nothing; at which time, also, the a
was extremely slow, being near its maximum.

3. *Diurnal.*—The diurnal variations of the declination were discovere
in 1722. In Europe, the north pole of the needle begins to move west
and continues moving in the same direction till an hour or two after noo
it returns and regains its original position at about 10 P.M., at which
night. It appears, then, that the westerly declination is greatest duri
part of the day. The amplitude of these movements is very small, an
ferent times of the year, being sometimes from 20′ to 25′, at other time
5′ or 6′. It also becomes less as we approach the magnetic equator: thu
of Rawak it never exceeds 3′ or 4′.

The periodic variations of the declination are the result of the
of two distinct variations,—one depending on the horary position of the
on his distance from the equator, the latter constituting the annual vari

Variations of the Dip.—The secular variations of the magnetic dip
amount than those of the declination. At Paris, in 1671, when the
observed, it was 73° 0′, and has since been continually diminishing; i
66° 35′. In London also the dip has continually diminished since 172
per annum. In August, 1821, it was 70° 2′·81; in May, 1838, it was
August and September, 1854, it was 68° 31′·13; it is now 68° 15′.

The dip likewise exhibits annual and diurnal variations, being, accordi
about 15′ greater in summer than in winter, and 4′ or 5′ greater before n

Variations of the Intensity.—It is not yet distinctly ascertained
magnetic intensity of the earth exhibits secular variations: indeed, the
the question is attended with very great difficulty, inasmuch as it req
needles used should preserve their magnetic power unaltered through

a condition scarcely possible to fulfil for any great length
indeed, by a peculiar method of observation which is inde-
needles used, that the magnetic intensity at Göttingen has
several years; but the time over which these observations
ort to warrant any general conclusion on the subject. It is,
hat the declination and dip should change at any place
variation in the intensity. By absolute measurements
April, 1857, it appears that the total force had increased
862, at the average rate of 0·00125 annually.

ensity are more easily observed. In studying these, it is
he variations of the horizontal and vertical components of
rizontal component exhibits an hourly variation, which is
tary variations—one diurnal, the other semi-diurnal. The
al variation increases with the latitude, and is nothing at
hrough which it passes depend on the angular distance of
neridian. In mean latitudes, the curve which represents
al component is similar to that of the diurnal variation of
behind it. The semi-diurnal period is scarcely perceptible
in distinctness at higher latitudes.

ical component of the intensity follow the same periods as
onents.

Perturbations of the Magnetic Elements.—The magnetic
ation-needle, frequently experiences accidental deviations,
ss from its normal position for various intervals of time,
s. Some of these disturbances may be traced to known
borealis, earthquakes, and volcanic eruptions. But few
le on the perturbations arising from the two latter causes,
ensible effects at small distances only. The deviations
disturbances rarely exceed a fraction of a degree, and the
e position as soon as the disturbing cause has ceased to act.
urora borealis with certain perturbations of the magnetic

$$\underset{\text{Maleic acid.}}{C^4H^4O^4} + H^2 = \underset{\text{Succinic acid.}}{C^4H^6O^4}$$

tion takes place when maleate of calcium is fermented in con-
ssaignes.)

r and *bromine*, maleic acid is converted into dibromosuccinic
another more soluble acid of the same composition, called iso-
cid. (Kekulé.)

ic acid is dibasic, forming *acid salts*, $C^4H^3MO^4$, and *neutral salts*,
ates bear considerable resemblance to the fumarates, with which
they may be distinguished by the difference of solubility between
l: solutions of the maleates are not precipitated by other acids,
ineral acid to the solution of a fumarate (sufficiently concen-
precipitate of fumaric acid is formed.

onium.—α. The *neutral salt* is obtained as a crystalline jelly by
solution of the acid with ammonia, and evaporating over lime
cohol added to the concentrated aqueous solution throws down
a white crystalline powder, which may be dried by repeated
and pressing between paper, but, when exposed to the air,
ous and deliquescent (Büchner). This salt does not precipi-
ichloride of iron, a character which distinguishes it from the
conitic acid.

btained by exactly neutralising a known quantity of the aqueous
en adding an equal quantity of the acid, and evaporating to the
gentle heat. It forms crystalline laminæ, which are permanent
s, and give off nothing at 100°: their solution evolves ammonia
y easily soluble in water, but not in alcohol.

um. α. *Neutral salt.* $C^4H^2Ba''O^4.2H^2O$.—1. Maleic acid forms
ulverulent precipitate, which disappears on the addition of a small
but reappears after a while in shining scales (Lassaigne).
he precipitate is converted into the crystalline scales, even with-
On adding a saturated solution of baryta-water to the concen-
e precipitate redissolves at first in the excess of acid; even when
has been added to neutralise the acid, the precipitate is but
w minutes, the whole solidifies to a tremulous gelatinous mass,
aluminium, which, after being pressed, dries up to small crystal-
crystals are obtained still more distinct on evaporating the
nault).—2. The salt is also obtained by adding carbonate of
eous acid, as long as effervescence continues, then filtering hot,
n to crystallise (Büchner).—3. The concentrated acid added
rows down a white crystallo-granular, neutral salt. Part of the
dissolved in the acetic acid which is set free, and may be preci-
his portion is also crystallo-granular, and has the same compo-
he salt crystallises from its aqueous solution on cooling, in small

tains the elements of bitter almond oil and formic ac
+ $2CH^2O^2$, and is related to benzoic acid (so far at least as
in the same manner as lactic to acetic acid, was discovered
Pharm. xviii. 310), who obtained it by heating bitter almon
acid, the hydrocyanic acid contained in the liquid being th
and formic acid, which, at the moment of its formation, uni
oil (Liebig, Ann. Ch. Pharm. xviii. 39). It is also p
fuming sulphuric acid on bitter almond oil (Laurent,
202), and by heating amygdalin with fuming hydrochloric a
Pharm. lxvi. 238.)

Preparation.—Bitter almond water—obtained by distilli
paste with 90 lbs. of water till 160 oz. have passed over,
liquid, and shaking up the distillate with the bitter almond
hydrochloric acid of specific gravity 1·12, and evaporated t
bath, till all the hydrochloric acid is expelled. The yel
smelling slightly of bitter almonds, leaves pure sal-ammonia
ether; and the ethereal solution yields by spontaneous eva
crystalline mass, which, when treated with water, leaves
having the odour of bitter almonds. The aqueous solution
less, and contains pure mandelic acid, which crystallises on
—2. When bitter almond oil is treated with one-third of
phuric acid, heat is evolved, the liquid becomes brown an
compact mass on cooling. The mass, when treated with wa
solid layer containing undecomposed bitter almond oil and
layer containing mandelic acid and excess of sulphuric aci
tallises from the latter on cooling (Laurent).—3. A so
hydrochloric acid is evaporated over the water-bath, and the
ether, which dissolves the mandelic acid. On evaporating
acid crystallises. (Wöhler, Liebig.)

Properties.—Mandelic acid forms a scaly crystalline mas
tallises sometimes in rhombic needles, sometimes in rho
having their acute angles truncated (Laurent); in plates
system (J. Heusser, Pogg. Ann. xciv. 637). It has a
almonds, and a strong acid taste, with a somewhat styptic a
with loss of water, into a yellow oil, which, on cooling, solid
(Winckler). When a solution of mandelic acid in stron
porated at a temperature above 100°, it becomes amorpho
solution with a small quantity of water, but is precipitated
form of a heavy yellowish oil (Wöhler). The acid is very
and *ether*.

Decompositions. The acid, *heated* above its melting p
odour, recalling those of white-thorn blossoms, hyacinth, a
in a distillatory apparatus to a temperature short of carboni

H. Deville (Compt. rend. xliv. 673) attributes the
nese prepared by Brunner's method, and that obtained
with charcoal, to the presence, in the former, of impu
adhering to the sodium, and to silicium from the fluo
that Brunner's manganese, when dissolved in hydroch
able residue of hydrated oxide of silicium; and Bru
that this residue, from 12 samples obtained in differen
to 6·8 per cent. By fusing the coarsely-pulverised m
chloride of sodium containing 1 per cent. of chlorate
silicium could be reduced to 0·1 per cent.; but Brunner
in the proportion of the silicium made any difference i
or lustre of the metal. (See MANGANESE, SILICIDE OF.)

Manganese enters as a base into two classes of compo
compounds, in which it is bivalent, and the manga
trivalent. It likewise enters as an acid-radicle into tw
nates and permanganates. Examples of these comp
table:—

Manganous chloride . .	$MnCl^2$ = 55
Manganous oxide . . .	MnO = 55
Manganic chloride . . .	Mn^2Cl^6 = 2 . 55
Manganic oxide . . .	Mn^2O^3 = 2 . 55
Manganate of potassium	MnK^2O^4 = 55
Permanganate of potassium	$Mn^2K^2O^8$ = 2 . 55

Manganese also combines with chlorous elements
peroxide = MnO^2.

brownish-black colour and reddish-brown streak: hardn
from Groroi in Mayence, Viedessos in Spain, and Cantee

Cupreous Manganese contains, besides hydrous oxides
per cent. oxide of copper, and 4 to 18 per cent. oxide of
Specific gravity 3·1 to 3·2. *Pelokonite* is a variety of
liver-brown streak. Hardness = 3. Specific gravity

Earthy Cobalt is a wad in which oxide of cobalt some
33 per cent.

Valuation of the Oxides of Mang

The numerous applications of the higher oxides of ma
tures, depend upon the quantity of oxygen which they
the action of acids, or—what comes to the same thing—
they are capable of eliminating when treated with hyd
seen from the following equations, which represent the
the dioxide, sesquioxide, and red oxide of manganese:

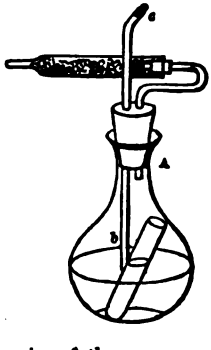
$$\underset{\text{Dioxide.}}{MnO^2} + 4HCl = MnCl^2 + 2H$$

$$\underset{\text{Sesquioxide.}}{Mn^2O^3} + 6HCl = 2MnCl^2 + 3H$$

$$\underset{\text{Red oxide.}}{Mn^3O^4} + 8HCl = 3MnCl^2 + 4H$$

Hence it appears that the quantities of hydrochloric a
quantity of chlorine, when acted upon by these three
2 : 3 : 4; or a given weight of hydrochloric acid, acted
yield quantities of chlorine in the inverse ratio of these

Moreover, as the sesquioxide and red oxide may be re
composition is concerned) as compounds of the protoxide
MnO^2; and $Mn^3O^4 = 2MnO + MnO^2$), it follows that th
ganese-ore may be regarded as proportional to the perc
contained in it.



The methods of assaying the oxides of manganese
heads:—1. The determination of the amount of oxy
acid.—2. The oxidation of oxalic acid.—3. The evolutio
acid.

a. The decomposition of peroxide of manganese by
represented by the equation:

$$MnO^2 + H^2SO^4 = MnSO^4 + H$$

The sample of manganese ore to be tested is heated w
small retort provided with a bent delivery-tube passing
jar, filled with and standing in an alkaline liquid, so th
may pass over may be absorbed, and the oxygen alone co
retort are heated to the boiling point, the heat being c
disengaged. The apparatus is then left to cool, and the
corrected for pressure, temper
vapour.

ack colour, tarnished brown on exposure. Streak green.
e the blowpipe it melts only on the thinnest edges.
oduced artificially in the dry way, by heating the peroxide
anhydride is disengaged and a green powder remains,
ith evolution of sulphydric acid. The same compound is
ate by decomposing acetate of manganese with sulphydric
with sulphide of ammonium.
manganese is obtained by passing the vapour of sulphide of
anic oxide ignited in a porcelain tube. The crystals are
aving a tinge of green and yielding a dingy green powder.
ganous sulphide soon turns brown by oxidation on exposure
n the air, it easily gives off all its sulphur as sulphurous
anoso-manganic oxide. Heated in hydrogen gas, it gives
onates when heated with nitre. Chlorine acts but slowly
ulphur. The hydrated sulphide boiled with potash, yields
anganous hydrate.
lves very easily in acids, even in acetic acid; sulphurous
lphite with separation of sulphur. When the precipitate is
utral metallic solutions, *e. g.* sulphate of cadmium, acetate
te of silver, sulphate of copper, &c., these metals unite with
ese is taken up in their place.
s definite compounds with the sulphides of potassium and
lt, $K^2S.3MnS$ or $Mn^3K^2S^4$, is prepared:—1. By fusing
hate with $\frac{1}{5}$ of its weight of lamp-black, and 3 times its
ssium and sulphur. A gentle heat is applied at first, till
expelled and sulphide of potassium formed; afterwards
redness. On cooling, a perfectly fused mass is obtained,
ulphide of potassium has been removed by cold water pre-
. leaves large dark red scales collected together in masses:
split, like mica, into thin, transparent, dark red laminæ.
de of manganese for the manganous sulphate, a similar
f less brilliant colour.—The scales, when moist, are rapidly
g black and opaque; but, when perfectly dry, they remain
e time. They are nearly insoluble in water, alcohol, and
ntly with nitre. Acids dissolve them, with rapid evolution
hen heated on platinum wire, they become covered with a
le of manganese. They are gradually dissolved by water
and sulphide of potassium, and manganous hyposulphite,
luble mixture of sulphur and manganic oxide. (Völker,

^{4}, obtained in a similar manner to the potassium compound,
ed needle-shaped crystals, resembling those of sulphide of
in most of their properties, but more readily oxidisable.
water, they rapidly become opaque and dark-coloured. If
over oil of vitriol in a vacuum, they rapidly absorb oxygen
erately dry; and the absorption is attended with so violent
at the crystals frequently take fire, and burn like a pyro-

the series, had been previously discovered by Flores Dor
then investigated by Strecker.

The connection between mannite and the hexylic grou
Erlenmeyer in 1861, by the conversion of mannite int
hydriodic acid:

$$\underset{\text{Mannite.}}{C^6H^8(HO)^6} + 11HI = C^6H^{13}I +$$

By this transformation the formula of mannite, which
was fixed with certainty.

The chemical character of mannite is that of a polyat
alcohol:

$$\left.\begin{matrix}(C^6H^8)^{vi}\\ H^6\end{matrix}\right\}O^6 : \text{type} = \left.\begin{matrix}H^6\\ H^6\end{matrix}\right\}O$$

Or, it may be regarded as hydride of hexyl in which 6
replace 6 atoms of hydrogen:

$$C^6H^8(HO)^6 : \text{type, } C^6H^{14}$$

It is closely related to the sugars, glucose becoming
nascent hydrogen, whether that hydrogen be a product
of sodium-amalgam on water:

$$\underset{\text{Glucose.}}{C^6H^{12}O^6} + H^2 = \underset{\text{Mann}}{C^6H^1}$$

Glucose is probably derived from the hydrocarbon C

On being heated to a temperature of 200°, mannit
mannitan (Berthelot):

$$C^6H^{14}O^6 - H^2O = C^6H$$

This conversion seems to be partial. Mannite is lik
by prolonged boiling with strong hydrochloric acid.

k of Saussure's researches, Boussingault entered upon
bject, conducting his experiments on a much larger scale, and
on to agricultural practice than had hitherto been attempted.
was also led, by the suggestive work of Saussure, to study
thy and saline substances upon the growth of different plants,
n have been continued to the present time. Boussingault's
ect were published in 1836, and in the year 1839 he had made
estigations, which—besides establishing the composition of
s of agricultural produce; the efficacy of various materials in
general relations between the composition of the crops obtained
he ordinary routine of practice in his locality—had led him to
at the carbon and nitrogen obtained in the several crops com-
nted to much more than was contained in the manure supplied
nd consequently, that those constituents must be derived in
osphere during vegetation; that those alternations of crops
mulations of carbon and nitrogen being gathered from the
ed upon the farm most largely, in the form of manure, were
that certain plants were better fitted for this purpose than
ue of manure was, to a great extent, indicated by the amount
which it contained. (See Boussingault, 1836, *Ann. Chim.*

aussure had already adopted the opinion that the carbon of
ent, derived from the atmospheric carbonic acid; and the same
d by Brongniart, in reference to the origin of the coal strata,
he humus theory. (Brongniart, 1837, *Compt. rend.*, Con-
re des Végétaux qui ont couvert la surface de la Terre aux
rmation, v. 403-415.)

the year 1840 that a comprehensive theory of plant-nutrition
ebig, with such perspicuity and force as to excite universal
ental proposition of that theory was, that the food of plants,
the chief mass of their substance is produced in vegetation, con-
cid, water, and ammonia. The chemical arguments by which
, in opposition to the prevailing opinion, that plants derived
oxygen, and nitrogen from humus, and from other vegetable
were conducted in such a convincing and logical manner, that
lly regarded as being entitled to the same honour in the
eory of plant-nutrition, as if the data on which it was based
l with himself. Liebig's researches on the phenomena of the
table materials afforded, together with the existing knowledge of
l life, the most conclusive evidence that the ultimate products of
rbonic acid, water, and ammonia, precisely those materials
od of plants. Moreover, these substances cannot be com-
as not to contain a far greater amount of oxygen than the
nts collectively consist, and which are produced in vegetation.
elimination of oxygen was a necessary feature of vegetation,
w light upon the known constitution of the atmosphere and
rbonic acid by growing plants; at once establishing a most
een the phenomena of vegetation and of animal respiration, and
al interdependence of the processes of animal and vegetable life.
he food of animals is provided exclusively by the vegetable
in the form of corn, roots, fruit, &c.; or indirectly, through
ife, as the flesh of herbivorous animals, the importance of a
stry of vegetation, in reference to the cultivation of plants as
nals, is self-evident. Consequently, Liebig's exposition of

Digitized by Google

his theory of plant-nutrition had especial reference to the
as the researches of Saussure, Boussingault, Lawes,
cuted in the same direction; and it was developed, in its appli
culture. (Liebig, 1840, *Chemistry in its Applications to A*

In order to illustrate fully the chemistry of manures, an
their use, as well as in the general routine of agricultural p
to give a brief statement of the general features of the ch
sidered from an abstract point of view, so far as the presen
will permit; then to describe the conditions which exer
influence upon vegetation, in regard to the object appertaini
and the different means adopted for the attainment of th
modification it receives by the various special circumstan
practised.

The ultimate result of the growth and development of
duction of a number of oxygenated and nitrogenous hydroc
sugar (ii. 855), gum (ii. 953), lignin (i. 818), fat (ii. 61
(ii. 873), legumin (iii. 568), fibrin (ii. 643), &c., which, in
modification, are universal constituents of all plants; an
analogous substances, which are special constituents of part
plant-organs.

The chief mass of the solid portion of plants consists of
main function of vegetation to produce them, and thus to
(See Nutrition.)

These constituents of plants were formerly termed, in a
substances, in conformity with the opinion that they coul
plant-organism, under the influence of vital action; and tha
in their chemical nature, from the compounds producible
belonging to the mineral kingdom, which were termed "ino
chemically from the proximate constituents of organise
animals—and from the derivatives of those compounds. I
has discarded that opinion, and with it the use of the term
expressive of a distinction which no longer represents a
the term "organic" is still conveniently applied to the
animals without involving such a distinction. (Gerhar
organique, i. 1–6.)

The materials from which the proximate constituents of
tation are few. According to the present state of knowledg
cipal source of the carbon; but in the case of some plants,
may possibly be derived from other carbon-compounds. (See

which the above substances are found in the ashes of plants is nt from that in which they exist in the plants themselves, and s to what that may be. The functions they perform in vegetation

et "mineral" to denote those constituents of plants which are not dissipated nguish them from the other constituents, and from other materials of plant-r, and ammonia—has recently been objected to by a high chemical authority, re, indicating confusion of ideas, since the epithet "mineral" applies "equally volatile and fixed, of plant-food" (Hofmann, *Chemical Products and Pro-hibition*, 1862, Class II. Section A, *Reports by the Juries*, p. 159). Since the s a subject concerning which it is especially desirable that any real or supposed ms, or of ideas, or of facts, should be stringently eradicated, and kept clear of, hat authority, abstain from such use of the term "mineral," substituting for it e those constituents of plants which, being earthy, are derived exclusively from the same rule in reference to the materials of plant-food which are supplied order to distinguish them from the other materials of plant-food—carbonic . In doing so, however, I may remark that the use of the term "mineral," has long been common among chemists; and will venture to suggest that there ience to authority, for abstaining from that use of the term which has been cus-epithet "mineral" unquestionably does apply "equally to *all* the elements, plant-food," still it does so only in a Natural History sense, not as synonymous inorganic," when used in its true sense as the antithesis to "organic." Nor mineral," in special reference to the chemistry of agriculture, been such as to o, or confusion with, the term "inorganic," when used in its true chemical the term "mineral" has been used in reference to that subject, during the last e specific designation of the ash-constituents of plants; and during the last those substances from the other "inorganic" materials of plant-food—carbonic . This is aptly illustrated in "*An Address to the Agriculturists of Great Britain, and Use of Artificial Manures*, by Professor Justus Liebig—Liverpool, 1845, "They are mineral substances, and as such, are indestructible by fire; and, ashes after the incineration of the plants, or of their parts." (See also . 173.) In fact, the term "mineral," so used, has a real advantage, in being m "inorganic," also used, in some instances, by Liebig and others, for the fixed, ash, or soil-constituents, as contradistinguished from the other materials acid, water, and ammonia—which, in a chemical sense, are also "inorganic," ly been called the "organic" materials of plant-food (See Liebig, 1840, *ons to Agriculture and Physiology*, pp. 3, 92, 114.—Boussingault, 1845, *Rural erly Review*, 1842, lxix. 336, *et seq.*—Lawes and Gilbert, 1847—64. *Journ.* xii. xvi. xvii. xviii. xxi. xiii. &c.—B. H. P.

are also little understood. The amount of them contain very small; but those which are constant and essential co being necessary to vegetation, must be regarded as indisp food. (See Kirwan, *op. cit.* 149, 157—Saussure, *op.* from the fact that plants will not grow to maturity und supply of the ash-constituents found in them under c necessity of the ash-constituents in vegetation is rendered fact that the fluids and organs of animals contain pre which are always found in fully-developed plants. (Bone, i. 619; Chyle, i. 961; Flesh, ii. 663; Gastr tissue; Nervous tissue.)

Moreover, the functions of these ash-constituents in th been so far traced, that there cannot be any doubt of thei the growth of animals—when they partly remain in t increase—and during the life of mature animals, when th cumulate in the body, but are eliminated, either direc with the rest of the daily food, in the excretions, after in the chemical process of animal life. (See Nutrition.)

The ash-constituents of plants have, therefore, a two-fold concerned both in vegetation and in animal life. Since the atmosphere, it is evident that the soil on which plant tant share in vegetation than that of affording merely m likewise the source of an essential portion of their food.

The mode in which the materials of plant-food are t the plant is twofold: partly by means of the leaves, a absorption of carbonic acid by the leaves and green part Priestley (1772, *Phil. Trans.* lxii. 166), and more fully de Sennebier, is one means by which plants may appropriat but whether they obtain nitrogen in the same way, has *The Vegetable Cell*, p. 86). The ash-constituents of plant organism only by the roots, and the structure of plants j are taken up in the state of solution in water (Mohl, *op.* ash-constituents, other food-materials are taken up by tivated plants—carbonic acid, ammonia, or other nitro from the decomposition of humus, and perhaps also carbo carbonic acid. (See Mohl, *op. cit.* pp. 80, 81.—Mulde *and Animal Physiology*, pp. 142–188.—Trinchinetti, *Radici*, pp. 55.—Boussingault, *Rural Economy*, p. 41

Scarcely anything is known as to the precise influenc and development of plants by the relative amounts of a sphere and from within the soil, or of the modification from such influences; though there are numerous fact experience, which apparently indicate that this circumstan importance in determining the character of the produce.

Nor are the special functions of particular materials plants any better understood, though experience appears ful in some other way than by directly contributing to plant; and it is far from being established that either th stances of which plants consist afford a quantitative ind which are necessary in their growth. This is especially th which are frequently grown with special objects, requirin ment of particular organs and constituents.

These circumstances render it very doubtful whethe during their growth, can be correctly measured by a kn alone, any more than it would be possible, in the case quantities of food required during their existence, mere qualitative and quantitative composition of the animal at

The various materials concerned in vegetation as plant- for the growth and development of the great majority of be replaced by anything else, not even by an increased a All must be supplied together; in the absence of any one are wholly incapable of supporting vegetation, and defi effect of the remainder.

if the land remained in bare fallow, or were converted a

The manure so produced by the internal economy of the
part of the nitrogen collected from the atmosphere by th
corn-crops, and used in feeding cattle, and would serve
furnish the augmented supply of nitrogenous air-food n
crop of corn.

The plants which are cultivated mainly with this obj
turnip, since it presents a striking contrast to corn-crop
most favourable to increase in the amount of produce, a
bilities and requirements, though it is inferior to legu
assimilating nitrogen from the atmosphere.

The amount of produce obtained under the system of
in this country is considerably higher with regard to all
countries; and though there is a difference in this respec
accompanying table may be taken to represent a fair a
tities of the several constituents of the different crops
termed a "four-course rotation," when a crop of turni
between two crops of corn.

The growth of the turnip as an agricultural crop, so
produce, is far more liable to be influenced by differen
with wheat. In the absence of rain, at a particular
number of the plants may die, and the acreage-produce
conditions of season be favourable, the amount of produ
20 or 30 tons per acre.

It has been supposed that the influence exercised by t
a fallow-crop, in restoring and augmenting the fertility o
increase of the wheat-crop, was referable to its comp
appropriating, by means of its large leaf-surface, the a
during its period of growth, and to its requiring but
materials from the soil. (See Davy, *Op. cit.* viii. 76, 7

That this is not the case, is evident from the amount
in the turnip, as shown in the table just referred to;
apparent by the following results of experiments by L
showing the amount of produce obtained by growing turni
on the same plot of land without manure.

s with the quantity of phosphoric acid contained in the turnip,
influence of phosphates on the growth of this plant cannot
the mere supply of material serving for the production of
ing a constituent of it. Though the amount of phosphoric
not larger than that in the wheat-crop, a direct supply of
s, from very general experience, to be much more influential
ent of the turnip than in the growth of wheat. Hence it is
the conclusion that it exercises some important and essential
r mode of development requisite in the cultivation of the
ding-crop, other than that which is represented by the amount
ned in the plants.
the supply of potash as a constituent of manure was not
ourable influence, either upon the mode of development of
the amount of produce; nor was it to be expected that this
of growing wheat without manure for several consecutive
ficient in supply of potash for the growth of a turnip-crop,
potash required by it is so much larger than that needed for

removed from the land in the turnip-crop does not cause
tituents to any sensible extent; for, excepting a small portion
luced by the use of the turnip in feeding live-stock, they are
in the manure; and if artificial phosphate-manures be em-
of turnips, the abstraction of this constituent from the land
be to a great extent compensated, if not covered.
ibed will serve to show that the cultivation of the turnip is
f the farm, by means of which nitrogen is stored up as part
the land, and, after having served intermediate purposes,
the important result of increasing the amount of produce
ans that concentration of the atmospheric supply of nitro-
ted, so as to furnish the corn-crops, during their period of
ch as they could otherwise obtain directly from that source
ability of appropriation.

to agriculture the theory of plant-nutrition which he con-
als furnished by Saussure, Davy, Sprengel, and Bous-
fundamental proposition, that plant-food consists solely of
monia, and the ash-constituents. In endeavouring to ascertain
y of manure; the mode in which it acts; the circumstances
thods of culture depend; and to establish rules for a rational
he addressed himself first to the questions, "What does the
the materials called manure contain?" as questions whose
l the starting-point of rational agriculture (*Chemistry*, &c., 1st
quiry his attention was mainly directed to the ash-constituents
parison of these with the constituents of soils and of manure
ated plants contained potash, phosphoric acid, and other ash
resence of these substances was constant in particular plants,
at every productive soil contained the same substances; that
rowth of a particular crop on the same land rendered it less
t crop until an interval of some years had been allowed to
t,—he came to the conclusion, that the capability of land to
o the presence in it of the ash-constituents of plants; that the
d nitrogen was dependent upon the presence of the ash-con-
limited by the available amount of them: consequently, that
as proportionate to the available amount of ash-constituents
edit. pp. 113–123). From the same data he concluded that
observed when a particular crop is raised year after year on
o the abstraction of ash-constituents from the soil. (*Op. cit.*

at animal excreta and the plant-remains in farmyard manure
onstituents as the plants which had been consumed as food;
ed a fertilising influence upon land naturally unproductive, or
tion of crops,—he concluded that the efficacy of this manure,
as the ashes of the food burnt in the bodies of animals, was
nts it contained; that its peculiar action consisted in and was
restoration of the ash-constituents, which the land was either
deprived of by previous crops. (*Op. cit.* pp. 176–187; *Address*
Great Britain, pp. 7–12.)
facts that the produce of land could be increased by manure,
he crop is directly proportionate to the quantity of manure
this effect was referable to the amount of ash-constituents
at if the supply of those constituents were greater than the
he previous crop, the amount of produce would be increased;
m were less than that, the produce would be reduced; and
to the quantity removed, the produce would remain constant.

ions as axioms to be observed in practical agriculture, Liebig
oduction of the organic constituents of plants from carbonic
a was determined by the presence of the ash-constituents pro-
ed (*Chemistry*, &c., pp. 196, 204); that its extent was limited
of them in the soil (*Op. cit.* p. 203); that the efficacy of
e amount of produce, by furnishing a supply of carbonic acid
led by the atmosphere, was subject to the same limitation
he amount of produce was so entirely independent of the arti-
that if only the ashes of solid and liquid excreta were supplied
ivated would derive their carbon and nitrogen from the atmo-
203–204); that the ammonia of the atmosphere, exceeding the
nts, was fully sufficient for all the objects of agriculture, even
one, the production of nitrogenous constituents of plants to
d animals. (*Op. cit.* pp. 54, 211.)
se substances was represented by Liebig as depending upon
of phosphates, which enabled plants to derive the requisite
phere—a source where the abstraction of that element was
ed by the ammonia resulting from the decay of animals and
other sources (*Op. cit.* pp. 147, 212). He also insisted that it
ortance for agriculture, to know with certainty that the arti-
a was unnecessary and superfluous for the growth of most
at the value of manure could not be estimated, according to
rance and Germany, by the amount of nitrogenous substances

manure, Liebig instanced the large quantity of nitrogenous substa
hay, milk, and flesh—on grass-land without any supply of nitroge
contrasted that fact with the smaller produce of nitrogenous cons
within the same period—as corn and roots—on land to which nitro
plied as manure in greater quantity than was contained in the p
referred to the export from Egypt of ammonia, obtained by burning a
the proverbial fertility of that country, where only the ashes of exc
mud, containing little nitrogen, had been used as manure for ages
cheese from Holland and Switzerland,—as rendering it perfectly cer
dution of nitrogenous constituents of plants was not proportionate
nitrogen supplied to the land in the manure: that the export of ni
was not exhaustive; because it was not the soil, but the atmosphe
nitrogen to plants: that it was impossible to augment the produ
supply of highly nitrogenous manure, or of ammonia-salts alone;
contrary, the capability of land to produce crops increased or diminis
portion to the ash-constituents supplied to it in the manure. (*Op.* c

The logical consequence of the opinions thus formed, was to re
stituents as the essentially, if not the only, effective portion of manu
It was insisted upon as a point of especial importance for the pract
deceive himself concerning the cause of the efficacy of manures (*Op.*
this respect the ash-constituents were compared by Liebig to the qu
bark, the iodine of burnt sponge, or the active principles of opium
Consequently, the ash-constituents of manure were the materials w
his view, it was essential for the farmer to supply to land artificially, i
the amount of produce. (*Op. cit.* p. 203, 211.)

The fundamental principle of rational culture, according to that vie
restoration of the ash-constituents removed from the land; and wheth
were made by applying excreta, or ashes, or bones, was regarde
indifference (*Op. cit.* p. 187). The particular kind of ash-constitue
manure, was to depend upon the kind of produce required; alkalis
of substances analagous to starch: phosphates for the production of
stances (*Op. cit.* pp. 193, 142, 144, 148). By the exact determinati
of ash in cultivated plants, and by the analysis of the ashes, the q
substances removed from land by crops was to be ascertained. Thu
to be enabled to keep a debtor and creditor account, for each of his fi
ash-constituents removed from the land, year by year; and to deter
the kind and quantity of the crops raised upon it, what substances an
of them were to be returned to the land, in order to restore its ori
fertility, or to be able to express exactly how many pounds of one or
was to be supplied to the land in order to augment the amount of pr
pp. 213, 214.)

Extending this view of the chemistry of plant-nutrition to the explana
operations of the farm, the practices of rotation, fallow, &c, Liebig,
his attention upon that particular aspect of the chemistry of agriculture
constituents of plants, soils, and manure are concerned, ascribed the inf
rendering land again capable of supporting the growth of corn, solely t
the ash-constituents requisite for that crop, by the decomposition of alka
land during the interval of fallow (*Op. cit.* pp. 118, 130–133). The
of burnt lime and burnt clay on some soils, was ascribed to the sam
He represented the advantages of rotation of crops as being, to so
the production of humus in the soil, but chiefly to the unequal
the different alternating crops for particular ash-constituents, and t
accumulation, during the greater part of the period of rotation, of thos
present in least available amount in the soil, and requisite for the gr
in larger amount than for the growth of the intervening crops. (*Op.*
169, 172; Berzelius—1844—*Jahresbericht*, xxiv. 333.)

This theory of the chemistry of agriculture was applied by Liebig
of artificial manure; and a patent was obtained by Muspratt for the
facture, as a communication from Liebig (*Improvements in the Manuf*
1845, Specification No. 10,616). These artificial manures were inte
the land exactly what was wanting for the growth of any particular
effect an economy which would be impossible while manure was a
nately—the useful and the unnecessary constituents together. But the
which these artificial manures were to secure, were to render the rota
fallowing unnecessary and superfluous, and to admit of one and
crop being grown, year after year, upon the same field—of a pere
without the necessity either of fallow or of a rotation of crops, which

clearly prove that the relative deficiency of nitrogeno
growth, was the main feature of the exhaustion, the d
amount of produce on the unmanured land, and of the i
stituents, if not also of the farmyard manure ash and of

These results, therefore, show that all hope of obtain
increasing the amount of produce of crops generally, by m
of the ash-constituents of the plants grown, must be en
regards agricultural practice, precisely the opposite cours
air-food by artificial means, in order to render the avail
effective. The artificial supply of nitrogenous air-food
full agricultural crop of corn can be obtained year after
since the sources of ammonia-salts at present availabl
pose, it is evident that a rotation of crops is an indispe
agriculture where the production of corn is the chief ob
to obtain a large amount of produce. The increased sup
atmospheric sources by the cultivation of fallow-crops,
feeding for the production of corn, must at the same
purchase, from extraneous sources, of nitrogenous manure
be practicable and profitable in particular instances. I
constituents, the artificial supply of nitrogenous manure
tuted for rotation, and cattle-feeding, so as to obtain large

It appears, therefore, that instead of reforming agricu
caused them to demonstrate the incorrectness of his
and the failure of those manures, from the applicatio
induced to anticipate such wonderful results, naturally p
which was sometimes expressed in a manner not alt
opposition to the views put forward by Liebig. Th
Agricultural Society of England, after remarking, in
mineral theory, hastily adopted by Liebig, had broken
the increase or diminution of crops being exactly propor
nution in the quantity of ash-constituents supplied to th
death-blow from the experiments at Rothamsted," went
principles of manure, ammonia was specially suited for
(Pusey—1850—*Jour. Roy. Agric. Soc.* xxii. 383-392.)

This expression of opinion by a practical farmer m
chiefly to the artificial supplies of manure required for
not by any means indicative of the idea that, in regard
sidered apart from agriculture, any one or other constitu
special value independent of others. The erroneous est
the opinions held in this country respecting manure, has
position that such an idea has been entertained, or else th
of the farmer's strictly technical view of this subject bei
of materials to be provided over and above those sup
ordinary practice, either from extraneous sources or by

That erroneous estimate has also given rise to much
which Liebig has manifested towards the conclusions a
Lawes and Gilbert, though virtually adopting thos
modifying his own views in accordance with them. It h
the general doctrine of plant-nutrition has been called in
case; nor has this general doctrine ever been disputed, ex

s consistent with the state of knowledge at that time. Of
e contrary, who had followed "the difficult and laborious course
tion by experiment," he remarked, that "his answers, though
stly trustworthy." (*Jahresbericht*, xxi. 236, 238.)
arly recognised by Berzelius between Liebig's mineral theory
oussingault's views on the same subject, has been fully con-
f experience. The former may be looked upon as a thing of the
n has been demonstrated by the entire failure of the attempts to
fundamental principle as to fertility and manure. The latter,
ne particulars by their development, and by the progress of re-
l in the main correct, and are supported by the extended results
nd Gilbert, in the series of experiments they have conducted
, during the last twenty years, with a strict regard to actual
nd in the laboratory, with all the refinement of modern methods

een Liebig's doctrine and the conclusions arrived at by Lawes
esult of their experimental researches, does not relate to the
nt-nutrition; but it relates solely to the ordinary system of
nd chiefly to that branch of the "mineral theory" of agriculture
which comprises the principles of manuring. Liebig ascribed
y of manure, solely to the amount of available ash-constituents
antages of rotation, mainly to the unequal requirements of
se substances.
on the contrary, have shown that fertility is not proportionate to
e ash-constituents in land; that the efficacy of manure is not
mount of ash-constituents it contains; that the exhaustion of
ractice of agriculture, consists chiefly in a deficiency of nitro-
that the advantage of rotation consists more in the accumulation
rbonaceous food-materials in the farmyard manure, than in the
ash-constituents taken from land by corn and fallow-crops; and
of cultivated plants cannot be measured merely by the results of

f the results thus obtained is not overrated by the opinion ex-
address of the President of the Royal Agricultural Society of
g the last twenty-five years, there has not been any addition
, which approaches, in importance, to the insight into the true
ng and manuring, obtained on the experimental farm at
mpson—1864—*Journ. Roy. Agric. Soc.* xxv. 4.)
usions and general views which have been arrived at by these
vehemently disputed by Liebig, who has sought to maintain
totally erroneous, and perfectly confirmatory of his "mineral
(Liebig—1851—*Letters on Chemistry*, 3rd edit.; 1855—*Prin-
istry*; 1863—*Natural Laws of Husbandry, Einleitung*, &c.—

sition has been arrived at by a singular process.
the "mineral theory" of agriculture comprised ammonia and its
al substances which were considered to determine the fertility of
f manure, and which it was, consequently, necessary to return or
r to maintain or increase fertility. (Liebig—1855—*Principles*
90.)
, is quite inconsistent with Liebig's original exposition of his
inted antithesis constantly maintained in all his writings, between
of plants, carbonic acid, water, and ammonia, whether furnished
phere, or indirectly from within the soil; and those materials
om the soil, which "are mineral substances, and as such are
and, consequently, remain as ashes after the incineration of the
es." It is also inconsistent with the general interpretation of
by other writers on the subject. (See Horsford—1846—*Genesee
Weissenborn—1847—*Farmer's Magazine*.—Schultze—1848,
Report, 1849.—Johnston—1848—*Jour. Roy. Agric. Soc. Eng.*,
4—*Traité des Amendments*, pp. 423, 623, 624, 627, 632.—Bous-
nomie Rurale, ii. 81.—*North British Agriculturist*, Nov. 7, 1855.)
that, in the specification of the patent which was the embodi-
eral theory" in relation to practical agriculture, neither ammonia
ded* among the mineral substances mentioned in the recipes and

In the criticism of Lawes' and Gilbert's experime
has assumed that they have regarded certain substances
materials of plant-food in an abstract point of view; but
Their experiments have only led them to consider tha
and in relation to the existing practice of agriculture, in
materials of plant-food acquire a preponderating value as
in the case of corn, become relatively deficient; or which
particular mode of growth, like phosphoric acid in the cas
the materials to be supplied artificially, not with the ob
resources of land, but in order to prevent these from lyin

Herein lies a difference which Liebig has either fail
disregarded; and it is a difference of the highest impo
accepts, in its full significance, the abstract theory of
concerns him: he also looks for its application to the ar
for rules by which his practice may be improved. Ther
suggestions for improvement have been more eagerly acc
or thirty years than in agriculture; but when such sug
wanting, the practical nature of agriculture demands thei

So it has proved with Liebig's application of his the
culture. Looking only to the ash-constituents of plants
has laid down rules for agricultural practice—he has pre
elaborate expositions of the various operations of culture,
failed to bear the test of experience.

But where the enquiry into this subject has been condu
and by a method at once more philosophical and more d
conditions of practical agriculture, as in the experiment
Lawes and Gilbert, the results obtained are calculated t
mate induction, by which principles of real value in rela
may be arrived at.

The customary routine of agricultural practice, howeve
ticular cases, has become established by observation and e
of the same mental functions which are employed in scien
exercise may be limited by the practical object in view
in reality, agricultural customs represent natural facts to
is yet competent to explain. To those who do not, like I
be "destitute of all understanding," the prejudices char
practice will, therefore, appear as the exponents of those
and other circumstances, which lie at the root of the pract
and unintelligible such prejudices and empirical rules ma
sideration of them, that a clue may be obtained to th
improvement of agriculture. The science which is to be
whose value will be recognised by farmers, must grow o
and the patient examination of its various details, and
grafting upon it. The accumulated data of ordinary expe
for its construction, and its doctrines must rest upon evid
probability. It may be a slow growth, but it must be a

Meanwhile, it is no reproach to the farmer if he adhe
knows by experience to have brought him certain result
another system until he has sufficient proof of its being r
with which he is familiar. This natural conservative ten
by the failures attending the premature application of
really the reason why farmers are in many cases averse
ments suggested by science. It is not because they are "de
or because they pretend to deny the existence of any c
doctrines and the phenomena concerned in agriculture, bu
able whether those doctrines really furnish the means
reason they prefer to be guided by tradition and experienc
cepts of scientific speculation. If there be an established
tween the practice of rotation with cattle-feeding, and the

ID. A crystalline acid produced, together with a chlorinated
chlorine on meconin. It contains 48·72 per cent. carbon, 4·07
e; crystallises in fine prismatic needles; is soluble in potash,
ld, easily in boiling water.

ACID. See MECONIC ACID, AMIDES OF.

). $C^7H^4O^7 = \left.\begin{matrix}C^7HO^4\\H^3\end{matrix}\right\}O^3$. *Mohnsäure. Opiumsäure.*—This acid
constituents of opium, was discovered by Sertürner in 1803
i. 183; lxiv. 65), but the more exact investigation of it has been
iquet (Ann. Ch. Phys. v. 282; li. 236; liii. 425), and Liebig
37; xxvi. 113, 147).
f preparing it is that of Robiquet, modified by Gregory
v. 43). Opium is exhausted with water at 38°; the extract is
ly pounded marble, evaporated to a syrup, and mixed with a con-
hloride of calcium, whereby the meconate of calcium is more com-
roportion as the liquids are more concentrated; and the preci-
water and pressed. [The mother-liquor serves for the preparation
f the precipitated meconate of calcium is now suspended in a
mercial hydrochloric acid and 20 pts. boiling water; the mixture
e short of 100°, and frequently shaken, till the whole is dissolved;
of calcium which separates on cooling is collected on linen, washed
of water, and redissolved, after pressure, in a mixture of 3 pts. of
20 pts. of hot water, avoiding ebullition. The liquid then yields, on
conic acid nearly free from lime, while the mother-liquor, in con-
of hydrochloric acid, contains scarcely any meconic acid. The
after being washed and pressed, are dissolved in 16 pts. of hot
ained through linen; and the filtrate is mixed with two-thirds of
f hydrochloric acid; on cooling it yields crystals of meconic acid,
l coloured. These crystals are suspended in cold water, neutra-
potassium, and heated to 100° with gradual addition of water in
to dissolve them; the solution, which solidifies on cooling, is well
ch runs off yields impure meconic acid when treated with excess
the expressed mass, which is not yet quite white, is redissolved
e quantity of boiling water; the solid mass obtained on cooling
this treatment is repeated till a pure white product is obtained.
nate of potassium is dissolved in 16 to 20 pts. of hot water; the
sium which separates on cooling is mixed on linen with a small
pressed, and redissolved in 16 pts. of hot water; the solution is
of hydrochloric acid; and the crystals of pure meconic acid
are washed with cold water, and recrystallised from solution in
quantity of boiling water. The mother-liquor expressed from
l yields a quantity of impure meconic acid when treated with
aper-filters [probably on account of the iron contained in them]
part of the process.
harm. lxxxiii. 350) heats the crude acid free from lime with
water, till the whole dissolves on addition of ammonia. The
difies in a crystalline mass, which may be freed by pressure from
r, and recrystallised two or three times from the smallest possible
ter. From the solution in hot water, the meconic acid separates,
f hydrochloric acid, in colourless laminæ, which are washed with
ecrystallised from boiling water.
of opium might also be treated in the first instance with ammonia
rphine, and the meconic acid afterwards precipitated by chloride
onia always precipitates a certain quantity of meconic acid from
n the form of a calcium-salt: hence the process is attended with

llises in micaceous scales or small rhombic prisms, containing
$3H^2O$), which it gives off at 100°, leaving a white, opaque,
s a sour taste, and reddens litmus strongly. It dissolves readily
ess easily in *ether*.

MELASSIC ACID. A black acid, produced, together wi
by heating glucose with caustic alkalis. When glucose is mel
saturated solution of baryta is added, a very violent action take
the first instance to the formation of glucic acid; but if the m
some time to a high temperature, it becomes continually dark
quence of the formation of melassic acid. On dissolving the
precipitating by hydrochloric acid, melassic acid is deposited in
in water, but soluble in alcohol. It contains, according to
to 61·0 per cent. carbon, and 5·3 to 5·4 hydrogen. The formu
61·9 carbon, 4·3 hydrogen, and 33·8 oxygen, agrees with these
carbon is concerned; but the amount of hydrogen found by e
for it.

MELENE. $C^{30}H^{60}$. *Paraffin of Wax.* (Ettling, Ann.
Lewy, Ann. Ch. Phys. [3] v. 395.—Brodie, Ann. Ch. Pharm
stance homologous with ethylene, &c., produced by the dry di
myricyl and of myricin. It may be prepared by subjecting bees'-
treating the product with potash, to saponify the fatty acid for
decanting the soap from the mixture of melene and oily hydroc
this mixture, which then gives off, first, the oily hydrocarbons,
when the heat is considerably increased. The product is purifi
crystallisation from boiling ether. It is generally necessary, h
lising it, to rectify it over caustic potash, in order to remove
oxygenated substance with which it is still contaminated.

Melene crystallises in perfectly white nacreous scales, inodo
specific gravity 0·89. It melts at 62° (Brodie), at 33·5° (Ettli
and solidifies in a waxy mass on cooling. Boils between 370
density, by three experiments, between 10·0 and 11·8: the dete
ever, rendered inaccurate by partial decomposition. It is inso
cold alcohol, but dissolves in boiling alcohol, and easily in ether,
and volatile.

Melene is not attacked by *potash* or *soda*, even at the boiling
does not attack it at ordinary temperatures; but on applying h
is carbonised, while the rest sublimes. It is but slightly attacke
Chlorine attacks it, producing, under certain circumstances, a bo
derable amount of chlorine.

from which it was formed were very dilute, in needles. Mellitic a
of barium forms, after a few seconds, a precipitate compos
crystals.

Mellitate of Calcium is obtained on mixing mellitate of am
of calcium, as an amorphous precipitate, which soon becomes
acid added to lime-water throws down white flocks soluble in hyd

Mellitate of Cobalt, $C^{12}(Co'')^3O^{12}.18H^2O$, crystallises fro
water in microscopic prisms.

Mellitates of Copper.—The *neutral salt*, $C^{12}(Cu'')^3O^{12}.12H^2$
amorphous precipitate, becoming crystalline after a while, on mi
of mellitic acid and cupric acetate. On mixing cold solutions
cupric acetate, there is deposited an *acid salt*, $C^{12}H^2(Cu'')^3O^{12}$
becomes crystalline. On adding a solution of cupric sulphate to
ammonium, a crystalline precipitate is formed consisting of *amm*
$C^{12}(NH^4)^2(Cu'')^3O^{12}.12H^2O$.

Mellitates of Iron.—The *ferric salt* is a cream-coloured p
hydrochloric acid.—*Ferrous salts.* Mellitate of ammonium forms
a greenish-white precipitate, which redissolves when the liquid
raising the temperature to the boiling point, a basic salt, $3Fe''O.$
precipitated in microscopic cubo-octahedrons of a lemon-yellow co
soluble in water, easily soluble in hydrochloric acid; assuming
when dry; and giving off all their water of crystallisation at 19

Mellitate of Lead. $C^{12}(Pb'')^3O^{12}$ (at 180°).—Bulky white p
nitric acid; obtained by adding the acid or the ammonium-salt
of lead.

Mellitate of Magnesium. $C^{12}(Mg'')^3O^{12}.18H^2O$.—Precipi
bonate of magnesium to a hot aqueous solution of mellitic acid, as
to a crystalline mass on cooling.

Mellitate of Manganese. $C^{12}(Mn'')^3O^{12}.18H^2O$.—Obtain
White powder, composed of microscopic needles; more soluble i
water, which dissolves only $\frac{1}{800}$ of it.

Mellitates of Mercury.—The *mercuric salt*, $C^{12}(Hg'')^3O^{1}$
obtained as a white granular mass by triturating mercuric oxi
and a small quantity of water, or by precipitating an alkaline me
nitrate.

The *mercurous salt*, $C^{12}(Hg^2)^3O^{12}.6H^2O$ (at 100°), is also obtai
as a white granular precipitate, very soluble in nitric acid, becomi

Mellitate of Nickel, $C^{12}(Ni'')^3O^{12}.24H^2O$.—When a hot sol
is saturated with carbonate of nickel, a green semi-fluid mass sepe
and becomes vitreous in contact with the air. This salt is ver
water, very freely in dilute hydrochloric and nitric acids. It gi
(4 at.) at 100°, and the rest at 300°.

Mellitates of Palladium.—Mellitic acid is perfectly neu
palladium; but the liquid does not yield any crystals, even whe
syrup; but on evaporation to dryness, it leaves a brown amorphous
mellitate. This salt dissolves in ammonia, forming a colourless li
poration, deposits colourless rhombic crystals, often macled in
containing $12NH^3.C^{12}(Pd'')^3O^{12}.6H^2O$. The whole of the water
together with a small quantity of ammonia. (Karmrodt, Ann. Ch

Mellitate of Palladium and Potassium crystallises from the mix
evaporated to a syrup, in nodular groups of indistinct prisms.
and sodium crystallises in macled triangular pyramids containin
dium. (Karmrodt.)

Mellitates of Potassium.—The *neutral salt*, $C^{12}K^6O^{12}.9H^2$
trimetric crystals, isomorphous with the neutral ammonium-salt
nation oP . ∞P . ∞P∞ . P∞ . P∞. Angle ∞P : ∞P = 114°;
oP : P∞ = 160°; ∞P : ∞P∞ = 123° nearly.

Acid salt, $C^{12}H^2K^2O^{12}.6H^2O$.—A hot solution of 1 at. of the n
mellitic acid yields this salt on cooling in large transparent right
often truncated on the lateral and terminal edges. It is more s
the neutral salt.

A compound of *acid mellitate and nitrate of potassium*, $4C^{12}H^2$
is formed by treating the preceding salt with nitric acid, or by mi
solution of neutral potassic mellitate with nitric acid, as long

ng the liquid till the precipitate disappears. The double salt then -sided trimetric prisms with dihedral summits, exhibiting the combi- ∞ . $\breve{P}\infty$. It has an acid taste, and is but slightly soluble in water. ellitate of potassium (perhaps $C^{12}H^3K^3O^{12}.C^{12}K^6O^{12}.18H^2O$) is men- ann and Marchand (J. pr. Chem. xliii. 129) as having been ob- n of a crystalline powder on adding mellitic acid to a concentrated utral salt. This powder redissolved in water yielded large nacreou g 20·63 per cent. carbon, 2·74 hydrogen, and 30·49 potash.

Silver.—The *argentic salt*, $C^{12}Ag^6O^{12}$, is obtained on adding mellitic of ammonium to nitrate or acetate of silver, as a white, crystalline, der, which the microscope shows to consist of transparent, colourless, ually having their angles truncated. When heated, it deflagrates iout exhibiting any electric excitement, as the oxalate does under nces. Heated to 100° in a stream of hydrogen, it blackens and gives e residue dissolves in water, forming a dark-brown, strongly acid dually deposits a mirror of metallic silver, leaving a solution of in mellitic acid. The brown or black residue obtained by heating evidently contains *argentous mellitate*. When argentic mellitate to 280° is heated with iodine, iodide of silver is formed, together talline sublimate, strongly acid, and very soluble in water.

Mellitate, $C^{12}K^3Ag^3O^{12}$, is deposited from a mixture of the com- ining nitric acid, in small, transparent rhombic prisms, in which the 21° 30′; $\infty P : \infty\breve{P}\infty = 119° 11'$.

when heated, first give off water and become opaque, then swell up plosion, and leave a residue of silver and potassic carbonate.

Sodium, $C^{12}Na^6O^{12}$, crystallises with two different proportions of centrated solution deposits needles containing 32·81 per cent. (12 at.) of which is given off at 180°. A solution saturated in the cold neous evaporation, large striated triclinic crystals containing 38·88 water, which they give off at 160°. (Erdmann and Marchand.)

Strontium.—White precipitate, soluble in hydrochloric acid, g mellitic acid to strontia-water.

acids derived from mellitic acid, see SUPPLEMENT, pp. 809–814.

ACID, AMIDES OF. (Wöhler, Ann. Ch. Pharm. xxxvii. rz, *ibid.* lxvi. 52.)—Two of these compounds are obtained by the ellitate of ammonium, viz. mellitimide or paramide, which has f triammonic mellitate minus 2 at. water:

$$\underset{\text{Acid mellitate of ammonium.}}{C^{12}H^3(NH^4)^3O^{12}} - 6H^2O = \underset{\text{Mellitimide.}}{C^{12}H^3N^3O^6}$$

cid, which is a mellitamic acid, derived from diammonic mellitate of straction of 4 at. water:

$$\underset{\text{Diammonic mellitate.}}{C^{12}H^4(NH^4)^2O^{12}} - 4H^2O = \underset{\text{Euchroïc acid.}}{C^{12}H^4N^2O^8}$$

e $(C^{12}O^6)^{vi}.H^{12}.N^6$ and mellitamic acid $\left.\begin{matrix}(C^{12}O^6)^{vi}\\ H^6\\ H^3\end{matrix}\right\}N^3O^3$ are obtained,

pricht and Scheibler, by the action of ammonia on neutral mellitate

euchroïc acid are obtained by heating neutral mellitate of ammonium long as ammonia continues to escape, and exhausting the residue with e then remains undissolved, and the solution contains euchroate of

id has already been described (ii. 601).

r Mellitimide, $\left.\begin{matrix}(C^{12}O^6)^{vi}\\ H^3\end{matrix}\right\}N^3$, is a white amorphous powder, insoluble cohol, but soluble in sulphuric acid, whence it is precipitated by water. h water to 200° in a sealed tube, or boiled for some time with water, ammonia, it is converted into acid mellitate of ammonium. By the restricted to a shorter time, it is transformed into euchroïc acid:

$$\underset{\text{Paramide.}}{C^{12}H^3N^3O^6} + 2H^2O = \underset{\text{Euchroïc acid.}}{C^{12}H^4N^2O^8} + NH^3.$$

al solution of paramide, mixed with nitrate of silver, forms a pitate, whose composition (at 150°) agrees best with the formula

According to Liebig, pure mellone or tricyanuramide may ing mellonide of mercury till the evolved mixture of cyanog three-fourths absorbed by potash.

Decompositions.—1. Mellone heated in a closed vessel is gr solved into a mixture of 1 vol. nitrogen gas and 3 vol. cyanog

$$C^6N^4 = 3CN + N.$$

According to Völckel, it is resolved hereby into nitrogen, c acid:

$$C^6N^6H^3 = 3CNH + 3CN + N^3$$

When mellone obtained from ammelide or chlorocyanamic disappears completely, giving off vapours which smell of ar acid, and deposit first a red, then a yellow, and lastly a re sublimate gives off ammonia when treated with potash, and pr The gaseous mixture evolved at the same time contains a ga sorbed by hydrochloric acid, another (cyanogen) which is al non-absorbable gas (nitrogen), the relative quantities of the ning of the experiment = 9 : 51 : 40, and at the end = 10 : 8 Gerhardt.)

2. Mellone heated in dry *chlorine gas* forms a white vol powerful odour, and attacking the eyes very strongly.—3. M in boiling *nitric acid*, continually giving off a gas which cont oxide, and is resolved into ammonia and cyanylic acid (ii. 2 long needles:

$$C^6N^4 + 3H^2O = C^6N^3H^3O^3 + NH^3. (1$$

Or,

$$C^6N^6H^3 + 6H^2O = 2C^3N^3H^3O^3 + 3NH^3. \text{ (Laurent}$$

4. Mellone dissolves in strong *sulphuric acid*, with evolution to the solution throws down a white substance different from

5. Crude mellone heated with *potassium*, or with *iodide, of potassium*, is converted into mellonide of potassium.

6. With a cold solution of *caustic potash*, it forms melloni the boiling heat is converted, with evolution of ammonia an into cyamelurate of potassium (ii. 187):

$$\underset{\text{Mellonide of potassium.}}{2C^6N^{12}K^3} + 9H^2O = 3NH^3 + \underset{\text{Ammelide.}}{C^6N^3H^3O^3} + \underset{\text{Cyame pota}}{2C^{}}$$

MELLONHYDRIC ACID. See the next article.

MELLONIDES. $C^6N^9M^3$, according to Gerhardt; C^6N latest experiments (Ann. Ch. Pharm. xcv. 257). Mellonide as already observed, by the action of potassium, or of iodide, of potassium, on crude mellone. This and the corresponding monium are soluble in water; the other mellonides are insol and are obtained by precipitation. The sodium- and ammon decomposing mellonide of barium with carbonate of sodium o

Mellonide of Ammonium crystallises in needles lik contains water of crystallisation.

Mellonide of Barium is obtained by treating the solu with chloride of barium, as a white precipitate which dissolv boiling water. The saturated solution deposits the salt i needles containing 20·87 per cent. water of crystallisatio 120°.

Mellonide of Calcium, obtained in like manner, is mor than the barium-salt. The crystals contain 18·05 per cent. at 120°.

The following are obtained as precipitates: *mellonide of ca* bluish-white; *cobalt*, peach-blossom-coloured; *copper*, parro yellow.

Mellonide of Hydrogen. Mellonhydric or *Hydromel* mixing a warm solution of mercuric chloride with mellonide of dazzling white precipitate of mellonide of mercury is obtain dissolves in dilute hydrocyanic acid, even in the cold. Sulph this solution throws down all the mercury in the form of sulp the hydrocyanic acid by a gentle heat, there remains an aque lonic acid, which has a strong acid taste and reaction, mix

rbonic acid from carbonates with effervescence, and yields, when ash, crystallised mellonide of potassium, exhibiting all the properties Liebig). L. Gmelin prepared the acid by decomposing the lead sulphydric acid.

of hydromellonic acid is evaporated, in vacuo or in the air, either gher temperatures, it deposits white films or flakes, and leaves a e residue, which redissolves but partially in cold water. The acid is etely decomposed under these circumstances; but the portion soluble a certain quantity of mellonide of potassium when saturated with ith alcohol. (Liebig.)

Iron.—The *ferric salt* is a dark-yellow precipitate; the *ferrous* ate with greenish reflex.

ead is a white precipitate which, after drying in the air, gives off r when heated in a bath of chloride of calcium. The air-dried salt . Gmelin's analysis, 42·45 per cent. lead, agreeing nearly with the $5H^2O$, which requires 42·58 per cent.

Magnesium is deposited, after some time, in small interlaced ure of mellonide of potassium and sulphate of magnesium.

Manganese is a white precipitate.

Mercury.—The *mercuric salt* is a white precipitate deposited on ng mixture of the solutions of mellonide of potassium and mercuric tions are mixed cold, the precipitate contains potassium. The salt es off nitrogen, cyanogen, and hydrocyanic acid; then nitrogen and portion of 1 vol. of the former to 3 vol. of the latter. (Liebig.)

lt, also obtained by precipitation, forms thick white flocks.

Platinum is a brownish-yellow precipitate.

Potassium.—Three of these salts have been obtained, viz the ^{3}, and the two acid salts, $C^9N^{13}HK^2$ and $C^9N^{13}H^2K$.

ide of potassium is obtained in many reactions besides those above viz. by the action of amidated compounds of cyanogen on potas- action of sulphocyanates on potassium-salts; and by the decom- yanate of potassium under particular circumstances. When, for lone (or calcined melam, &c.) is added to fused sulphocyanate of le of potassium is produced, with evolution of sulphide of carbon, ellone, but also from the elements of the sulphocyanate. Again, of copper is added to melting sulphocyanate of potassium, sulphide , and mellonide of potassium remains mixed with metallic sulphide. ssium is also formed by heating sulphur with ferrocyanide of n the mixture used for preparing sulphocyanate of potassium is too formation being due to the mutual action of the sulphocyanates of formed in the first instance. All these modes of formation of ium from sulphocyanates become intelligible on observing that a ins the elements of sulphide of carbon, a metallic sulphide, and a

veral compounds in which mercury forms part of a base or radicle pes ammonia and ammonium, *e.g.* bromide of mercurammonium ide of tetramercurammonium, $(Hg'')^4N^2Cl^2$. Trimercuramine, in the free state.

LLOYS or **AMALGAMS OF.** Mercury is capable of uniting etals, forming compounds called amalgams, some of which are are solid. The solid amalgams appear to be for the most part of nstitution; while the liquid amalgams may be regarded in many s of definite compounds in excess of mercury, inasmuch as when they hamois leather, mercury containing but a small quantity of the other n, while a solid amalgam, frequently of definite atomic constitution, ven in the solid amalgams, however, the affinity by which the two ther is but feeble; for Joule has shown that many of those which ers of atoms of their component metals may be partly decomposed to very strong pressure, part of the mercury being then forced out, taining a larger portion of the other metals remaining behind. In the formation of amalgams is attended with little or no contraction ase of silver and copper, however, the contraction is considerable— and a few others, it is perceptible. The union of mercury with m is attended with considerable evolution of heat.

ombining mercury with other metals are:

state or finely divided, the action sometimes takin
sometimes requiring the assistance of heat.

2. The introduction of metallic mercury into the s
part of the mercury then passing into the solution a
which then unites with the rest of the mercury. I
be more easily effected by means of an amalgam
sodium for example. A sodium-salt is then formed,
on the mercury and unites with it.

3. The introduction of various metals into solu
example. In the case of silver, gold, or platinum,
mercury from its solutions, the action must be
zinc or iron into the solution, and bringing it in co
form a voltaic circuit: thus a drop of solution of me
gold will not amalgamate it; but if an iron wire or
the wetted surface of the gold, a white spot of ama
point of contact.

4. By placing the metal to be amalgamated in
dilute acid, a voltaic circuit being also formed in th
is wetted with dilute sulphuric acid, and mercury p
ately amalgamated.

Several amalgams are used in the arts. Tin amalg
amalgams of gold and silver in the processes of gildi
amalgams, copper-amalgams, and an amalgam of
stopping teeth; an amalgam of zinc and tin, somet
used for coating the rubbers of electrical machines.

Aluminium-amalgam?—Klauer (Ann. Ch.

thus obtained is silver-white, soft and dull; is attracted by the
it contains zinc (?), and becomes covered with black, pulverulent
exposed to the air.

m may be formed: 1. By immersing a piece of copper-foil in a
of mercury.—2. By triturating mercury with common salt and
turating 2 pts. of mercury, 2½ of verdigris, and 1 of common salt
y of heated vinegar, which must be renewed as it evaporates, and
m by washing.—4. By mixing 1 pt. of finely-divided copper—ob-
ne oxide with hydrogen, or by precipitation from the sulphate by zinc
rops of mercurous nitrate, and then triturating with 3 pts. of mercury,
is formed (Berzelius).—5. Mercury placed in contact with the
taic battery, and covered with solution of cupric sulphate into which
s, becomes perfectly saturated with copper (Grove, Phil. Mag. [3]
o Joule (Chem. Gaz. 1850, p. 339), the amalgam thus obtained has
Hg; and the same definite compound is obtained by dissolving
and removing the excess of the latter by strong pressure (Chem.
When, however, the pressure is very strong, or is continued for a
ting amalgam contains more than 1 at. Cu to 1 at. Hg (Joule,
82).—6. Copper amalgam may also be formed by treating a solu-
te with sodium-amalgam (Klauer), or zinc-amalgam (Damour).
mersed in a mixture of cupric sulphate and sal-ammoniac forms a
llow amalgam of copper and ammonium, which soon decomposes.
am used by the Parisian dentists for stopping teeth is prepared by
s sulphate (obtained by heating together 10 grms. of mercury and
lphuric acid) and finely-divided copper (obtained by precipitating a
. cupric sulphate in 10 or 12 times its weight of water, with metallic
are triturated together under hot water for 20 or 30 minutes; the
f, and the trituration repeated with fresh quantities of water as long
any blue colour. The amalgam is then dried, again triturated, then
rmed into small cakes, which become quite hard in 36 to 48 hours.
oduced contains 3 pts. copper to 7 pts. mercury. An easier mode of

HIDE OF. See MERCURY-RADICLES, ORGANIC.

UORIDES OF. Mercury forms two fluorides, corresponding in chlorides.

ride. $(Hg^2)''F^2$. Berzelius obtained this compound as a sub-ercurous chloride, by heating the latter with fluoride of sodium. xamined by Finkener (Pogg. Ann. cx. 142), who obtains it by itated calomel to a solution of silver-fluoride (prepared by digest-ith hydrofluoric acid); the whole of the silver is then gradually liquid evaporated over the water-bath, yields small yellow fluoride. An easier mode of preparation is to add recently carbonate to hydrofluoric acid, which dissolves it completely n of carbonic anhydride, but on addition of a larger quantity ioride as a heavy, light yellow, crystalline powder. From a solu-luoric acid it is deposited in indistinct (apparently cubic) crystals. is partly dissolved by water, partly decomposed into mercurous acid. It is blackened even by moist air, especially if exposed ecomposed when heated above 260° in dry air, mercury subliming, becoming corroded. From the solution of the compound in *sh* throws down mercurous oxide; *ammonia*, a black precipitate nercury and quickly turning grey, while the filtered liquid le and soon deposits a white mass containing mercury, ammonia, rcurous fluoride is decomposed in like manner, by the prolonged *onia*, into metallic mercury and a mercuric compound. It slowly turning black and being converted into fluoride of mercuros-".F^2.

oride, $Si^2(Hg^2)''F^6.2H^2O$, is deposited from the solution of mer-drofluosilicic acid, in transparent, colourless, prismatic crystals.

de. $Hg''F^2$. Mercuric oxide added to hydrofluoric acid is con-yellow powder, consisting of an oxyfluoride, and by repeatedly ed with hydrofluoric acid, mercuric fluoride is deposited as a s containing $HgF^2.2H^2O$. The same product is obtained by xide to a large excess of aqueous hydrofluoric acid (containing F) (Finkener, Pogg. Ann. cx. 628). According to Frémy lvii. 5), mercuric fluoride is obtained in long colourless hydrated owever, contaminated with hydromercuric fluoride or mercuric evaporating a solution of mercuric oxide in excess of hydro-; however, did not obtain crystals in this manner.

fluoride decomposes at 50°, giving off hydrofluoric acid together ng the **oxyfluoride**. It is permanent in dry air at ordinary decomposed by *water*, yielding mercuric oxyfluoride and a ric acid containing a small quantity of mercuric oxide. A fluoride in hydrofluoric acid mixed with a slight excess of er some time in the cold, and immediately when heated, a white which, when washed and dried over sulphuric acid, consists of oxyfluoride $2NH^3.Hg^2F^2O$. (Finkener.)

ide and *Silico-oxyfluoride*.—A solution of mercuric oxide in ields by evaporation small pale yellow needles, which were as mercuric silicofluoride; but according to Finkener they fluoride $Hg''Si^{iv}F^6.Hg''O.3H^2O$. This compound is resolved by y temperatures, into a soluble acid salt and an insoluble yellow

ic oxide in hydrofluosilicic acid, concentrated so far that oxy-o separate, and then left to itself at a temperature below 15°, bohedral crystals grouped like steps, probably consisting of silicofluoride $Hg''Si^{iv}F^6.6H^2O$. They are very unstable ightly heated, but effloresce over sulphuric acid. (Finkener.) curic fluoride with *fluoride of ammonium* is produced, according g mercuric fluoride with aqueous ammonia.

IDES OF. Mercury unites with iodine in three or four **mercurous** and **mercuric iodide** analogous to the chlorides, ercuric iodide, and perhaps a **periodide**. The two elements ibination, when large quantities are employed, being attended of temperature.

s are, for the most part, colourless; the basic salts yellow:
etallic taste, and are violent acrid poisons. They are decom-
y at the boiling heat, with separation, generally of a basic salt,
ric oxide, as from the nitrate, the solution retaining sometimes
ometimes a free acid. Hence H. Rose (Pogg. Ann. cvii. 298),
as the weakest of all basic oxides, no other oxide being preci-
ns of its salts by water. In the solution of mercuric chloride,
tate, either of oxide or basic salt, the oxide being precipitated
y strong bases, since mercury, like the other noble metals, has a
orine than for oxygen. Conversely, mercuric oxide precipitates
lutions of their chlorides, but not of their oxygen-salts. Those
ed to a solution of mercuric chloride, do not form a precipitate
loride, are thrown down by mercuric oxide from their solutions
ereas those which precipitate mercuric oxide from the solution of
wn down by that oxide from the solutions of their own chlorides.
s are not precipitated from their solutions in hydrochloric acid
m solution of *manganous chloride*, the manganese is completely
time, as manganous oxide (manganous sulphate, on the other
). From solution of *chloride of lead*, mercuric oxide throws
m *chloride of zinc*, the red-brown oxychloride (sulphate and
ecomposed by it). From the *chlorides of nickel* and *cobalt* it
les of those metals, the former completely, the latter for the
s are not decomposed). From *ferrous chloride*, ferrous oxide
uric oxide immediately turning black, but becoming red again
l contains mercuric chloride, if the quantity of mercuric oxide
to form an oxychloride; and the insoluble residue consists
nd a ferric oxychloride, produced by the reaction, $2Hg''O + (Fe^2)^{vi}O^2Cl^2$. From *ferric chloride*, mercuric oxide in excess
on as ferric oxide, forming an insoluble mercuric oxychloride
te is not altered by it). From *cupric chloride* it throws
cupric oxide; cupric sulphate is decomposed by it after a long
oxide being converted at the same time into a solid lump of
and basic cupric sulphate. (H. Rose.)

MERCURY-RADICLES, ORGANIC. (Fra
lxxxv. 381.—Dünhaupt, Chem. Gaz. 1854, pp. 263
xxxix. 57.—Buckton, Ann. Ch. Pharm. cviii. 103; c
Frankland and Duppa, *ibid.* xvii. 415.)

Mercury unites with alcohol-radicles of the series,
amyl,—also with allyl C^3H^5,—forming compounds in
element. These compounds may, in fact, be regarded a
compounds, such as the chloride, bromide, &c., by subs
either the half or the whole of the chlorine, &c., : thu

Mercuric chloride.	Mercuric chlorethide.
$Hg''\{^{Cl}_{Cl}$	$Hg''\{^{C^2H^5}_{Cl}$

When both atoms of chlorine, &c., are completely r
product is an indifferent compound (a neutral merc
with acids or acid elements. But when only half of
radicle is thus replaced, there results a saline compo
which easily undergoes double decomposition, and in
chlorine ($Hhg''C^2H^5$ for example), plays the part of a

The two kinds of compounds here considered, are
same manner as mercaptan and ethylic sulphide are rel
for example, being the ethylic ether of mercuric chlor
is the ethylic ether of mercaptan.

Mercaptan.	Ethylic sulphide.
$C^2H^5\}$	$C^2H^5\}$
$H\ \}S$	$C^2H^5\}S$

There is, however, this difference between the tw
mercuric chlorethide and its analogues, in which only
on alcohol radicle, the remaining chlorous atom is
chlorous radicle, whereas, in the corresponding sul
hydrogen-atom, being basylous, is most easily replac
elements.

If the mercury in these compounds be regarded as
only mercury and an alcohol-radicle must be repre
HgC^nH^{2n+1}; and those which contain iodine, chlorine, &
with mercuric iodide, chloride, &c.; *e. g.* HgC^2H^5, *mercu*
or $HgC^2H^5.HgI$, *iodide*, or rather *mercuriodide, of merc*
of representation affords a much simpler and more sati

by four different processes:—1. By the action of merc
radicle, under the influence either of diffused dayli
bination then takes place, and an iodo-mercuric compo
Strecker):

$$Hg'' + C^nH^{2n+1}I = Hg''\}$$

2. By the action of mercuric chloride on a zinc-com
product being an organo-mercuric compound, contain
radicle, or 1 at. alcohol-radicle and 1 at. chlorine, ac
reagents is in excess (Buckton):

$$Hg''Cl^2 + Zn''(C^nH^{2n+1})^2 = Hg''(C^nH^{2n}$$
$$2Hg''Cl^2 + Zn''(C^nH^{2n+1})^2 = 2\left[Hg''\{^{C^n}_{Cl}\right.$$

3. By the action of mercuric chloride on the organ
3 at. of an alcohol-radicle; thus bismutho-triethide
chloride yields bismutho-dichlorethide and mercuric ch

$$\overline{Bi}(C^2H^5)^3 + 2Hg''Cl^2 = \overline{Bi}(C^2H^5)Cl^2$$

4. By the action of sodium-amalgam on the iodides o
of acetic ether (Frankland and Duppa). The reacti

$$2C^nH^{2n+1}I + Na^2 + Hg'' = Hg''(C$$

The acetic ether appears to take no part in the reacti
quantity at the end of the process. Nevertheless, the
ether (viz. methylic acetate or ethylic formate) is essen
inasmuch as sodium-amalgam does not act on the alco
in contact or heated with them; neither is the react

Digitized by Google

n adding a few drops of acetic ether, it takes place imme-
tion of sodium in the amalgam must be very small, not ex-
f mercury. If a solid or semi-solid amalgam is used, the reaction
fferent manner.

best mode of preparing the alcoholic mercury-compounds, yield-
large quantities of the methyl-, ethyl-, and amyl-compounds.
and iodomethide are obtained with tolerable facility by the
entioned; but the corresponding amyl-compound was obtained
quantities barely sufficient for its identification. On the other
ric ethide and methide by the second method, requires the previous
rge quantities of the corresponding zinc-compounds, and the pre-
amylide has never been attempted by a similar process, on account
of preparing zinc-amyl. (Frankland and Duppa.)

ounds containing 2 at. of an alcohol-radicle, are easily converted,
mine, chlorine, or iodine, into compounds containing only 1 at.
e.g.:

$$+ \quad Br^2 \quad = \quad \underset{\text{Mercuric brom-ethide.}}{Hg''(C^2H^5)Br} \quad + \quad \underset{\text{Ethylic bromide.}}{C^2H^5Br}$$

exerted by acids, *e.g.* by hydrobromic acid:

$$+ \quad HBr \quad = \quad \underset{\text{Mercuric brom-ethide.}}{Hg''(C^2H^5)Br} \quad + \quad \underset{\text{Ethylic hydride.}}{C^2H^5.H.}$$

l, in like manner, the products are mercuric sulphatethide,
lic hydride.

action is exerted by certain salts. When, for example, mercuric
ercuric ethide, the latter gives up half its ethyl for half the
r, producing 2 at. mercuric chlorethide:

$$''(C^2H^5)^2 \quad + \quad Hg''Cl^2 \quad = \quad 2Hg''(C^2H^5)Cl.$$

, the mercuric compounds containing only 1 at. of an alcohol-
verted into others containing 2 at. of an alcohol-radicle: thus,
d zinc-ethyl act upon one another in such a manner as to yield
odide of zinc:

$$I \quad + \quad Zn''(C^2H^5)^2 \quad = \quad 2Hg''(C^2H^5)^2 \quad + \quad Zn''I^2.$$

ounds containing 2 at. of an alcohol-radicle are converted into
c-compounds when heated with excess of finely-granulated zinc
uppa, Chem. Soc. J. xvii. 29):

$$^{2n+1})^2 \quad + \quad Zn^2 \quad = \quad Zn''(C^nH^{2n+1})^2 \quad + \quad ZnHg.$$

Allyl-compound.

lylide. $Hg'' \left\{ \begin{matrix} C^3H^5 \\ I \end{matrix} \right.$.—When iodide of allyl is agitated with
stalline mass is formed, from which the mercuric iodallylide may
lcohol or ether. The alcoholic solution deposits it on cooling in
turn yellow when exposed to light, especially on drying. It is
old alcohol, nearly insoluble in water. It sublimes at 100°, in
ic plates, melts at 135°, and solidifies on cooling to a yellow
nore quickly and strongly heated, it decomposes for the most part,
as residue, and giving off a yellow sublimate.

ion is decomposed by nitrate of silver, the whole of the iodine
dide of silver; oxide of silver likewise decomposes it, forming
strongly alkaline solution which, on evaporation, yields a syrupy
s, soluble in water, and forming salts with acids. This product
allyl-hydrate, or hydrate of mercurallyl, $Hg'' \left\{ \begin{matrix} C^3H^5 \\ HO \end{matrix} \right.$. (Zinin,
i. 393.)

le is easily decomposed by hydriodic acid and by iodine. The
epresent respectively the action which takes place in each case:

(1). $HgC^3H^5I + HI = HgI^2 + C^3H^6$
(2). $HgC^3H^5I + II = HgI^2 + C^3H^5I.$

for preparing tritylene, by means of iodide of allyl, mercury, and
pends on the first of these reactions. (Linnemann, Ann. Ch.

ic solution of the hydro-ethide with alcoholic bromine. It resembles (Dünhaupt.)

bonethide. *Carbonate of mercurethyl.*—Prepared by decomposing h carbonate of silver at a gentle heat. It crystallises with difficulty mposed by heat. Acids decompose it, with evolution of carbonic haupt.)

orethide. $Hg''(C^2H^5)Cl$.—Obtained by the action of mercuric o-triethide (Dünhaupt); by precipitating the aqueous solution of the oride of sodium (Strecker); and by treating mercuric ethide with f mercuric chloride in excess (Frankland and Duppa). It is *water*, dissolves sparingly in *ether*, and in cold alcohol, but freely and crystallises therefrom in light iridescent laminæ, having a silvery ted to 40° it sublimes in thin laminæ, without previous fusion, but o a clear oily liquid, and then evaporates completely. Heated on rns with a faint flame, diffusing a very unpleasant odour. (Dün-

anethide. $Hg''(C^2H^5)Cy$.—Formed by saturating an alcoholic ic hydrethide with strong hydrocyanic acid. Crystallises readily. en heated in a tube, it emits a vapour which has an extremely ttacks the respiratory organs strongly, and appears to be highly naceous residue is left in the tube. The cyanide dissolves readily in (Dünhaupt.)

hide. $Hg''(C^2H^5)^2$.—This compound is prepared:—1. By the yl on mercuric iodethide. Dry pulverised mercuric iodethide is antities to zinc-ethyl contained in a retort through which a stream ng, the mixture being incorporated by stirring, and, as soon as the ted—which may be known by the stirring rod ceasing to fume on —the product is distilled till nothing but gases pass over. The distil- avy liquid, mixed with a little ether, is then redistilled with a slight , to ensure complete decomposition of the iodethide, then washed with and afterwards with water, and rectified (Buckton).—2. By heating ercuric chloride, avoiding an excess of the latter, as otherwise mer- will be formed: the slight excess of zinc-ethyl is decomposed by parated oxide of zinc dissolved out by dilute hydrochloric acid.

f 16 pts. by weight of iodide of ethyl and 1 pt. of acetic ether is um-amalgam, the flask being alternately agitated to promote the ed into cold water to moderate the rise of temperature. The com- ion is known by the subsidence of the temperature, and the absence s of precipitated iodine, when a few drops of the clear liquid re- sk are boiled with nitric acid. When the quantity of iodide of been increased so far as to render the ethereal liquid pasty, thereby ently intimate contact with the amalgam, it is advisable to place the th, and distil off the more volatile portion of the contents, to be fresh amalgam.* If this distillation be deferred till the residue has hick and pasty, it will not be necessary to repeat it, as the distillate ntly fluid up to the termination of the reaction. The product mixed es into two layers, the ethereal liquid either floating or sinking in n of iodide of sodium, according to the degree of concentration or hen successively treated with alcoholic potash, washed with water, of calcium, and rectified. (Frankland and Duppa.)

so little malleability or ductility that they cannot be rolled into wire.

esistance to forces which tend to tear asunder, either by tension, ng, is another character which metals possess in very unequal ately connected with molecular condition, and is in some way y and ductility. It is largely influenced in particular metals by nce of certain admixtures; by the manner in which they have pe, and by temperature. In general it is reduced by increase of ome cases it is increased within a certain limited range of tem- se of iron (see COHESION, i. 1078). Some metals possess but a tenacity, and are then termed brittle—as zinc, antimony, and

capability of a bar of metal to recover its original shape and ng bent or stretched, is also a character connected with tenacity . It varies much in different metals.

differ very widely in the degree of *hardness* they possess, or are by sudden cooling or otherwise. Some are so soft as to admit of wax (potassium and sodium), others are capable of scratching nd (steel, chromium). The presence of small amounts of various rbon, silicon, &c., in metals, often communicates to them con- As a general rule, a metal is more brittle in proportion to its

of assuming a *crystalline structure*, generally belonging to the some other form of the regular system; antimony and arsenic hedrons. Metals occurring native are frequently crystallised. The e structure in a metal, considerably influences its tenacity. It is d by an increased degree of brittleness, and those metals which tallised are, as a general rule, the most brittle. Crystalline s assumed by metals, while in the solid state, under the influence t, of percussion or of vibration, and other mechanical actions, and uced is often of importance in relation to technical applications 7). Metals may often be crystallised by slowly cooling them in a ien partly solidified, pouring off the remaining liquid metal (see AD, iii. 478). Metals often assume a crystalline structure when solutions of their saline compounds, and some can be crystallised arsenic).

oïds in general present a marked difference in their power of con- d heat; the conductivity of metals for electricity is greater than stances. It varies considerably in different metals, and to some ual metals, according to their molecular condition, temperature, bsence of foreign admixtures.* The purer and softer the metal, ctivity: the higher the temperature of the metal, the less its con- ctivity of some metalloïds is increased by elevation of temperature. *Lehre vom Galvanismus und Electromagnetismus*, i. 180.— , Proc. Roy. Soc. xi. 516.)

oïds differ in their electrical relations, the former being, as a class, latter electro-negative. The distinction, however, is only one of present similar differences among each other. (See ELECTRICITY,

y in their capacity for heat. The specific heat of sodium amounts t of bismuth, lead, mercury, or gold. The conductivity for heat hough metals generally possess a comparatively high degree of . (See Despretz, Compt. rend. xxxv. 540.—Wiedemann and h. Phys. xli. 107.)

ble presents some of the principal physical characters of the tary metals and metalloïds, so far as they have been deter- es the numbers given are only approximative. It must also be existence of these characters, and the degrees in which they are ar substances, are sometimes due to the molecular condition of the n to any inherent peculiarity. This is more especially known to metalloïds, several of which are polymorphic, as sulphur, phospho- licon, &c. (See DIMORPHISM, ii. 331.)

).
characters and relations of metals and of metalloïds, there are
t as in their physical characters. These differences, however, are
the functions which the substances of one or other class perform,
with other substances, than by the capability of direct combination
hich is considerably influenced by various physical conditions, such
ate of aggregation, &c.; hence also this mode of chemical action
regarded merely as a phase of some more general dynamic pro-
s the exercise of a peculiar force, inherent in the different elementary
CHEMICAL AFFINITY, i. 850 *et seq.*) But in any case, the existence
nds, and their characters in relation to other substances, must be
of the same mutual activity which determines chemical combina-
elementary substances are more or less capable of existing in a state
nation with each other; but those possessing this capability in the
, as a rule, either the most opposite in their general chemical rela-
le of assuming special functions in relation to certain others. The
ces possessing the most universal capability of existing in combina-
nd of direct combination, are fluorine? oxygen, sulphur, chlorine,
d some of the metals.
xygen, which present the most decided differences in their general
may be taken as typical of the two classes of elementary substances
talloïds—the one representing the basylous, and the other the
ts of compounds. (Graham.)
hlorous characters of the elementary substances are not however abso-
s in the case of fluorine and oxygen. On the contrary, they vary ac-
of substances existing in combination. Thus, for instance, chlorine
th basylous in relation to oxygen, but chlorous in relation to hydro-
elementary substances; again, among the metals which are generally
elations to other substances, some are capable of existing in combi-
in relation to which they are then feebly chlorous.
ubstances consisting of two elementary radicles, their chemical
tions to each other generally approximate to the basylous or chlorous
ess in proportion to the relative preponderance of one or other of
one of the constituents. Thus, for example, in water the relatively
rous characters of hydrogen and oxygen are so nearly balanced
stitute of any chemical activity as an independent substance, and
s exhibit is, according to circumstances, sometimes basylous, as in
rate, &c., and sometimes chlorous, as in potassium-hydrate, calcium-

acid, however, the chlorous character of chlorine relatively to
that of oxygen, in such a degree that this substance is decidedly
to those substances with which it can exist in combination. But
id, though chlorine is basylous relatively to oxygen, that substance
n its compounds. In soda and sodium-chloride, on the contrary,
cter of sodium exceeds that of hydrogen, relatively to oxygen and
degree that the former is highly basylous, and the latter slightly so.
tivity of compounds as independent substances, is not by any means
hat of their constituents; thus, for instance, nitrogen is one of the
ubstances, but its compound with hydrogen is a powerful alkali,
npounds with oxygen are powerful acids.
in which two elementary substances are combined also influences
cters and relations of the compound. Thus, in sodium-peroxide,
s much oxygen as soda does in proportion to sodium, the basylous
rs, and this compound is destitute of any chemical activity as an in-
ee. Again, manganous oxide is highly basylous, and manganic oxide
he peroxide is indifferent, and the higher oxides are chlorous. In
ompounds of nitrogen and of chlorine, bromine, iodine, &c. with
cidedly chlorous in proportion to the amount of oxygen they contain

Oxides. All the elementary substances, except fluo
combination with oxygen, in one or several proportions

The physical characters of oxides are generally ve
constituent basylous radicles. Among the metalloïdal
ordinary conditions, as carbonic oxide, carbonic acid,*
sulphurous acid, &c.; some are liquid, as nitrous acid;
sulphuric acid, silica, &c. Among the metallic oxides,
volatilisable, as arsenious acid, antimonious oxide; th
infusible and insoluble in water. Formerly metallic
their production was termed calcination. (See GAS

Many oxides occur native in great abundance; thus
carbonic acid is a constituent of the atmosphere and of
stances. Silica also is very abundant both in the state
as a constituent of numerous minerals and rocks. Sul
a constituent of various minerals, as gypsum, selenite
occurs in the lagoons of Italy, and in some minerals:
distributed throughout the mineral kingdom, in small
abundantly in plants and animals. Among the metalli
the alkalis are probably the most abundant; exist
minerals and rocks. Among the compounds of the
oxides of iron, manganese, and zinc are the most a
combination with carbonic acid, silica, &c.

The chemical relations of the oxides are as dive
stances. Among the metalloïdal oxides containing the

rine in hydrochloric acid. (See SALTS; and ACIDS, i. 39; ALKALI, 9.)

taining the largest proportions of oxygen are decomposed at various he action of heat alone, yielding oxygen-gas and lower oxides. id, which is readily decomposed by heat, most of the other higher loïds which are known in a separate state, are capable of supporting nperature without decomposition. The sesquioxides and peroxides rally decomposed by heat into oxygen and lower oxides, and all the ld, platinum, &c., are decomposed by moderate degrees of heat into e respective metals. Some oxides, on the contrary, combine with a oxygen, either at the ordinary temperature, as for instance man- oxides, or when heated in contact with oxygen or atmospheric air, e. This change takes place most readily in some cases when the ation with water, or when water is present.

be decomposed to a greater or less extent by the simultaneous action e other substance capable of combining with oxygen, and of abstract- de operated upon, so as to form an oxide of greater stability under This **reduction**, as it is termed, is complete when the whole of rated from the basylous radicle, and partial when there is only a ced. The most powerful reducing agents are the alkali-metals, oxide, and carbon. Even carbonic oxide is decomposed by potas- with the aid of heat. The oxides of the metalloïds are mostly ction by carbon with the aid of heat. Among metallic oxides those d, bismuth, &c., are completely reduced by hydrogen at a red heat; anese and uranium, &c., are but partially reduced; oxide of zinc with e lower oxides of chromium, manganese and uranium, and the oxides alkali-metals are not affected by hydrogen. In the reduction of y means of carbonic oxide or carbon, the metal eliminated often a state of combination with it. At very high temperatures, carbon les which are not affected by hydrogen, as for instance soda and eat.

tion of a metallic oxide by carbon is effected at a comparatively low nic acid is formed; but when it takes place only at a very high nic oxide is produced.

f metallic oxides may also be effected by heating them with metals ess readily reduced. Thus potassium reduces several metallic oxides, ferric oxide at a red heat; but at a white heat, potash is decomposed ult in this latter case may be due to the volatility of potassium at and the consequent removal of small portions reduced under the ponderating mass of iron, so that this action takes place repeatedly f the potash is decomposed, and without any possibility of action ium and oxide of iron.

heat and reducing agents upon compound oxides, such as sulphates, here may be produced a compound of the metal with the chlorous n-sulphide, by heating to redness a mixture of the corresponding on. If the radicle of the chlorous constituent of the compound does the metal under the circumstances, it may be volatilised in the ide, as in the reduction of nitrates.

l oxides, such as carbonates, nitrates, &c., are decomposed by the at, the acid being eliminated either unaltered or decomposed, and e remaining either in the same state as it existed in the original a higher state of oxidation; thus ferrous carbonate yields by rric oxide and a mixture of carbonic oxide with carbonic acid.

and metalloïds do not, under any known circumstances, combine en; for example, gold, platinum, nitrogen, chlorine, bromine, iodine, rs are capable of combining directly with oxygen, some of them at ures, as for instance sodium, potassium, &c.; others like copper, iron, hosphorus, &c., when heated to temperatures differing for each. In t combination with oxygen is attended with evolution of heat, and pidly, it is also attended with evolution of light. (See COMBUSTION,

ondition of substances capable of combining directly with oxygen, ich the facility with which the combination takes place. A state of n is most favourable, while a compact condition is most opposed to cially when the resulting oxide is infusible at the temperature combination, and forms a protecting crust over the surface of the pulverulent copper, heated to about 450° C., takes fire in oxygen gas,

The solvent action of earthy silicates upon metall
effecting the separation of the ferrous oxide, produce
and certain products of metallurgic operations, such
a mixture of ferric oxide, cuprous oxide, and a sil
subjected to reducing melting, the cuprous oxide an
the former yielding metallic copper, and the latter
the silicate, forming a fusible slag which admits of the
collecting together in mass below it. Manganic oxide
in the same manner as ferric oxide; and any easily r
as cuprous oxide.

Silicates also exercise a solvent action upon the g
example, when an ore consisting of galena and g
ferric oxide and suitable slags, the latter dissol
reduced to ferrous oxide, which reacts with the lead
the sulphur to sulphurous acid, which volatilises, w
the same time, separates the lead from combinatio
forms iron-sulphide. In this case all the differe
operations take place together.

As a general rule it may be stated, that when m
oxide which is more easily reduced, and of silicates
silica, are subjected to reducing melting, the least
by the silicate and forms slag, while the more easily

Digitized by Google

ever, it is necessary that the silicate should be present in suffi-
at its melting point should be higher than the temperature at
reducible oxide is decomposed, and lower than that at which the
xide is decomposed. If there were a deficiency of silicate, the
xide would not be converted into slag, and a portion of it would
llic state. If the silicate melted before the cuprous oxide had
the latter would pass into the slag; and if it did not melt till
been partly reduced, the copper would be mixed with iron.
ral be more easily fusible, or at most not less fusible than the
melting operation; but the actual degree of fusibility will vary
g to the temperature requisite in the operation. The following
ary of the more important results obtained by Plattner in his
sibility of various silicates and slags:—

TOMIC WEIGHTS AND CLASSIFICATION OF.

d metals.—The received atomic weights of the non-metallic hlorine, bromine, and iodine, or 19, 35·5, 80, and 127, are merely of each of them which have the same gaseous bulk as the unit of four halogen elements, which may be considered as chlorous or elec- ies of hydrogen, have the characteristic property of replacing nother, in a great variety of compounds, by an equivalent substitu- olume, atom for atom. The fluoride, chloride, bromide, and iodide mposed of equal volumes of halogen and hydrogen united without olume or atom of chlorine, for instance, uniting with one volume or o form two volumes of hydrochloric acid, HCl. These two volumes ecule of hydrochloric acid, which is usually regarded as a chloro- olecule of hydrogen, HH, and taken as a convenient standard of -volume molecules in general.

ium, sodium, potassium, rubidium, cæsium, and silver e above halogen elements, and accordingly may be looked upon as -positive varieties of hydrogen. Their received atomic weights, K 39, Rb 85, Cs 133, and Ag 108, express the relative quantities of can displace 1 part by weight of hydrogen to unite with 35·5 parts ne. Now it is found by experiment that 7 parts of lithium, 23 parts of potassium, and 108 parts of silver have substantially the as one another; so that 7 parts of lithium and 108 parts of silver, b or evolve the same amount of heat in undergoing the same ment of temperature. The specific heats of the atomic proportions , and by analogy of rubidium and cæsium also, are moreover sub- with the specific heats of the atomic proportions of chlorine, , and may be expressed with sufficient accuracy for our present mber 6·2, in comparison with the specific heat of water taken as ity. Each of these metals unites with chlorine in but a single to form a chloride expressible by the general formula M'Cl, de- pe HCl; and the specific heats of these several chlorides and of romides and iodides, approximate to the number 12·4, giving a for each atom in the molecule.

he monad metals, though more or less volatile at high tempera- iently so to allow of their densities in the vaporous state being riment. Their theoretical vapour-densities, however, are assumed heir respective atomic weights, and their molecules are accordingly al two-volume standard. One or two of these metals, more parti- sodium, have been made to combine with the organic radicles but the resulting methides and ethides have not been obtained in n, and *à fortiori* have not had their vapour-densities determined.

inciples on which the determination of atomic weights must logically
cussed very fully in a previous article (*vide* ATOMIC WEIGHTS), which it
was necessarily written long before the date of its publication. It
d, that although in the author's opinion, the arguments in favour of
ic weights of the metals now under consideration, were not at that time
t to warrant the adoption of a hasty change in old established usages,
osal being then of very recent introduction, it was not improbable that in
objections to which it was liable would be more or less satisfactorily ex-
ile further potential arguments might possibly be adduced in its support.
has since actually taken place; for although the objections to the pro-
n now be regarded as altogether overcome, yet the arguments in its
rate so largely as to leave no doubt whatever about the ultimate
adoption. Before considering *seriatim* the reasons for and against
ubling of the atomic weights of these metals, it may be observed
, just as there are monatomic, diatomic, and triatomic chlorous
ld we expect to have monatomic, diatomic, and triatomic basylous
ls. It would, moreover, be extremely strange if while triad and tetrad
antly met with, there should exist only one or two well-known dyad
ust as among chlorous elements, the distinction between monatomic
ms was recognised long before the distinction between monatomic and
o is it natural that among basylous elements also, the distinction
ic and diatomic metals now proposed for adoption, should not be
long after the distinction between monad and triad metals had been
ly acknowledged.

eat.—If we represent the chlorides tabulated above, as dichlorides,
proportions of metal combined with two atoms of chlorine in their
les have their specific heats expressed by the number 6·2, just as have the
s of metal united with one atom of chlorine in undisputed protochlorides,
roportions of metal united with three atoms of chlorine in undisputed
t if we continue to regard the chlorides in question as protochlorides,
f metal contained in their respective molecules will have only half the
e proportions of metal contained in the molecules of undisputed proto-
In other words, with the doubled weights and formulæ, the atoms
metals will have the same specific heats, whereas with the old atomic
l have only half the specific heats, of the atoms of chlorous dyads,
and selenium; of chlorous and basylous monads, such as bromine,
nd silver; and of chlorous and basylous triads, such as phosphorus,
, and gold. Moreover the specific heats of their respective chlorides,
ichlorides, will agree with the specific heats of undisputed proto- and
his particular, that, divided by the number of atoms in the molecule,
ld the constant 6·2. Thus the ascertained specific heat of corrosive
(200 + 35·5 × 2) is 18·67, which divided by 3, gives the quotient 6·22.
—The argument from atomic heat is admitted to have great force,
fficient to be absolutely decisive of the question, inasmuch as the ato-
non-metals, boron, carbon, and silicon, are not under any circumstances
s great as the atomic heats of their metallic congeners. It being
ible to accord the same specific heats to the atoms of all the elements, it
able that the atomic heat of certain metals should differ from the
the remainder, that magnesium and mercury, for instance, should
ie atomic heat of sodium and silver. Then the molecule of chloride
l, for instance, would have the specific heat of its constituent atoms,
hile the molecule of chloride of silver AgCl, would have the specific
tuent atoms, 6·2 + 6·2 = 12·4.

ar Volume.—Mercuric chloride and mercuric ethide, if represented
e formulæ $HgCl^2$ and $HgEt^2$ respectively, have the same molecular
corresponding monadic compounds, hydric chloride HCl, and hydric
ectively, and as the corresponding triadic compounds, arsenic chloride
ic ethide $AsEt^3$ respectively. The gaseous volumes of zinc-chloride
loride have not been ascertained, but the gaseous volumes of their
hides and methides agree with the ethide and methide of mercury, in
of their respective vapour-densities being the halves of their atomic
ey are represented as dyadic compounds, thus:

2 vols.	2 vols.	2 vols.
H Cl	$Hg''Cl^2$	$As'''Cl^3$
HEt	$Hg''Et^2$	$As'''Et^3$
EtCl	$Zn''Et^2$	$B'''Cl^3$
	$Sn''Et^2$	$B'''Et^3$

Digitized by Google

In other words, the volatile chlorides and ethides o dyadic, will have the same molecular volume, whereas will have only half the molecular volume of undisputed protethides and triethides, &c.

Objection.—The above argument from molecula rather less weight than that from atomic heat: for by and its congeners the formulæ which bring their m with the molecular volumes of chloride of hydrogen, forced to accord to the metals themselves, molecul with the molecular volumes of the elements, hydroge

2 vols.	2 vols.
HCl	H^2O''
HEt	Et^2O''
EtCl	Cl^2S''
HH	OO
ClCl	S S
BrBr	SeSe

In other words, the proportions of mercury, of cad which combine with two atoms of chlorine, or eth gaseous volume of the proportion of hydrogen whi chlorine, or ethyl, or methyl, and consequently doubl of oxygen and sulphur respectively which combin proportion of nitrogen which combines with three methyl. But just as the diatomic chlorous elements same gaseous volume as, and not double the volu elements, chlorine and bromine, so should we expect mercury and cadmium, to have the same volume as, the monatomic basylous metalloïd, hydrogen. This by comparing the molecules of mercury, cadmium, &c oxygen, free sulphur, &c., which are divisible in the molecules of the diatomic compound radicles carbo ethylene, &c., which are indivisible; thus:—

2 vols.	2 vols.
$H^{\prime 2}$	Hg''
$Cl^{\prime 2}$	Cd''
$O^{\prime\prime 2}$	$(CO)''$
$S^{\prime\prime 2}$	$(SO^2)''$
$Se^{\prime\prime 2}$	$(C^2H^4)''$
$N^{\prime\prime\prime 2}$	$(C^6H^6)''$

Whatever value may be accorded to this explanat discordance undoubtedly remains, that the atomic pr mercury and cadmium, have double the volume of sulphur.

γ. Double Salts.—The characteristic property lity, when united with one and the same monaton radicle by two successive substitutions, and of the monatomic radicles. Now this property of combini certainly very well exemplified by the class of metal as shown in the list of compounds tabulated below, w

$(Hg\mathrm{Cl})^2$	Mercury, dichloride
$Hg\mathrm{Cl}.Hg\mathrm{Et}$	„ chlor-ethid
$(Hg\mathrm{Et})^2$	„ diethide
$Hg\mathrm{Et}.Hg\mathrm{Me}$?	„ etho-methi
$Zn\mathrm{Et}.Zn\mathrm{I}$	Zinc iodo-ethide
$Ca\mathrm{Cl}.Ca\mathrm{ClO}$	Bleaching powder
$Sr\mathrm{NO}^3.Sr\mathrm{C}^2\mathrm{H}^3\mathrm{O}^2$	Strontium acetato-nit

ber of these double compounds possess a moderate degree of sta- of them, as the double halogen ethides and methides, are among and stable of metallic salts. The relation of the organic compounds rsenic to one another is evidently parallel to that of alcohol and amines, as shown below:

s.	Dyads.		Monads.	
Cl^3As	H^2O	Cl^2Hg	HCl	ClNa
$EtCl^2As$	EtHO	EtClHg	EtCl	EtNa
Et^2ClAs	Et^2O	Et^2Hg		
Et^3As				

alcohol, the basylous radicles, hydrogen and ethyl, are held together n, so in the hydrato-nitrate of lead, the two chlorous radicles are iatomic lead (Williamson, Chem. Soc. J. xvii. 211). Accordingly, place diatomic oxygen by monatomic chlorine, we get two distinct

$$PCl^3Cl^2 + HEtO'' = PCl^3O'' + HCl + EtCl.$$

in our lead-salt we replace diatomic lead by monatomic silver, we rgentides, thus:

$$g^2 + HO.NO^2Pb'' = SO^4Pb'' + HOAg + NO^2Ag.$$

-The force of this argument is much diminished by remembering ubted monatomic elements and groupings have the property, though t, of combining with two distinct monatomic radicles. Chlor-ethide nstance, Hg″EtCl, may be written $(Hg^2)EtCl$, and compared with ilver, $(Ag^2)I.NO^3$, argento-chloride of sodium, $(Cl^2)AgNa$, hydro- ium, $(F^2)HK$, hydro-acetate of potassium, $(2C^2H^3O^2)HK$, and many s, in which we have the monatomic elements silver, chlorine, fluorine, sic acetic acid, &c., combined with two different monatomic radicles, the stability of these compounds, save and except some of the hydro- very feeble character. Moreover, in contrasting the properties of and diatomic ethylene, and comparing the undisputed monad metals nd the metals under discussion with the latter, there is one point, at e importance in which the comparison does not hold good. The ibasic acid is found to be replaceable by two different monatomic he same radicle at two successive stages, whereas it is replaceable by c radicle only, and that at a single operation. Thus the diatomic nay be substituted for the hydrogen of oxalic acid to form oxalate of C^2O^4, which is the only derived oxalate of ethylene hitherto known; natomic radicle ethyl we have acid oxalate of ethyl, $(C^2H^5)'HC^2O^4$, f ethyl, $(C^2H^5)^2C^2O^4$, potassic oxalate of ethyl, $(C^2H^5)KC^2O^4$, &c. In monatomic radicle ethyl does, and the diatomic radicle ethylene does nd double ethers or salts of dibasic acids; and a similar difference of ifested by monatomic and diatomic chlorous radicles, such as acetyl lyl $(C^2O^2)''$, in their relation to a diacid base such as glycol. Now oes not seem to be any decided difference in this particular between of metals. One member, at any rate, of the first group—namely, or scarcely does, while several of the members of the second group form well-defined acid and double salts, as exemplified by the acid m, $BaHC^2O^4$, potassio-oxalate of zinc, $ZnKC^2O^4$, acid carbonate of HCO^3, gay-lussite, $CaNaCO^3$, dolomite, $MgCaCO^3$, acid sulphate of auberite, $CaNaSO^6$, acid selenite of calcium, $CaHSeO^3$. &c. &c. Such novinates of calcium and barium cannot properly be adduced in illus- although for some purposes, sulphovinic acid may be regarded as a of ethyl and hydrogen, comparable with acid sulphate of potassium, y a conjugated compound analogous to the sulphamic and sulpho- instance, and consequently as much monobasic as the formic, acetic, themselves.

ever, be contended in any way that the property of forming acid and n dibasic acids is incompatible with the diatomic character of the em; for, indeed, there is no sufficient reason why the atom of a dyad bind together two atoms of dibasic sulphuric acid, for instance, just e diatomic radicle sulphuryl binds together two atoms of dihydric

ce, Ag^2S, in the regular system, the native form or copper-glance is iso-
silver-copper-glance, AgCuS, in the trimetric system. Miargyrite and
er are similarly constituted compounds, $AgSbS^2$ and $CuSbS^2$ respectively,
te $Pb''CuSbS^3$, and red silver Ag^3SbS^3, are similar and isomorphous.
lity of cuprous into cupric compounds constitutes, indeed, the only
rity of behaviour distinguishing them from the similar compounds of
as they continue to be cuprous compounds, the resemblance between
silver analogues is as great as that between the corresponding con.
two associated metals. But despite the analogy of cuprous to silver
stance, and of permanganic to perchloric acid, it has been proposed to
ecular formulæ of all cuprous and permanganic compounds, and conse-
ess them by formulæ dissimilar to those of their respective silver and
ues. By this means the formulæ Cu^2Cl^2 and $Mn^2H^2O^8$, for instance,
e brought into harmony with the law of even numbers, but at a very
of simplicity and analogy. Fully admitting the great and not generally
ue of Laurent and Gerhardt's law, it must yet be remembered that
hed chemists themselves pointed out its inapplicability to the perissad
the iron metals, save by admitting for each metal two different atoms
two different symbols; and it may also be asked whether the received
sing Laurent and Gerhardt's law might not be advantageously modified
dictum as the following, that "in every compound the sum of the
quivalencies is an even number."

er and manganese, though usually dyadic, are associated with monadic

lensity being the half of its atomic weight, its molecule is referrible to the ume standard. The dichloride and trichloride are also volatilisable com- eir vapour-densities have not been determined. That of the trichloride, l probably present the same peculiarity as the analogous aluminic and les; and judging solely by vapour-density, the compound would conse- o be represented by the formula Cr^2Cl^6. Chromous salts correspond us salts in their general behaviour, and especially in their absorption with production of dark brown compounds. They have, however, a olour more like that of cobalt salts. Alkaline sulphydrates throw down tate of chromous sulphide, and caustic alkalis a pale coloured precipitate ydrate, soluble in sal-ammoniac and ammonia. The tendency of this to become peroxidised greatly exceeds even that of ferrous hydrate, as radual deoxidation of water with liberation of hydrogen. The double ome and potassium, $K^2Cr''(SO^4)^26H^2O$, is isomorphous with the similar c. Chromic and ferric compounds again present a general similarity of igh with some well-marked differences. Chrome-iron $Fe''(Cr''')^2O^4$ is ith magnetic oxide $Fe''(Fe''')^2O^4$; chromic oxide $(Cr''')^2O^3$, with hæmatite mic alum $KCr'''(SO^4)^2.12H^2O$, with iron alum $KFe'''(SO^4)^2.12H^2O$, &c. similar compounds of ferricum, chromic oxide is decomposed by fusion d alkalis into chromate and an inferior oxide; chromic hydrate is solutions of caustic alkalis; while chromic salts react with sulphide of roduce chromic hydrate and sulphuretted hydrogen, though this last possibly be only one of degree depending upon the difficult reducibility pounds: for it is doubtful at least whether the precipitate produced by monium in ferric salts is other than a mixture of sulphur and ferrous omic anhydride $Cr^{vi}O^3$, the most characteristic of all the compounds of well defined salts having the same general formula as the manganates, lphates XM^2O^4. Its resemblance to vanadic anhydride, a compound e pentad group, has been already noticed (p. 968).

s usually classed with the iron metals, for although possessing but little en to them, it has still less to any other group of elements. The for- m-compounds, and the atomic weight of uranium must be regarded for not finally determinable, since the analytical results cannot yet be ny considerations derived from vapour-density, isomorphism, specific chemical analogy. The proportion of uranium which unites with 35·5 ne in uranous chloride, is found to be 60 parts, and accordingly the of the metal may be fixed at 60, or 120, 180, 240, &c. The ready anous chloride is in favour of its molecule containing more than one, n more than two atoms of chlorine; while the high specific gravity of would seem to associate its atomic weight with those of such heavy sten, specific gravity 17·6, atomic weight 184; gold, specific gravity eight, 196·5; and platinum, specific gravity 21·5, atomic weight 197; rrelation of specific gravity with atomic weight is undoubtedly subject ies. Altogether, it seems most advisable to assume that the atomic um is 240, and that the formula of its subchloride is U^2Cl^6, while that oride is UCl^4, and that of uranic oxychloride $U^{vi}O^2Cl^2$. Aqueous de and uranous salts in general have a marked green colour, but rown gelatinous hydrate, soluble in carbonated alkalis. They are mposed by the earthy carbonates, with evolution of carbonic anhydride. lack precipitate with sulphide of ammonium, and oxidise readily by r. Uranic salts are of a lemon-yellow colour, and possess in a egree the property faintly shadowed forth in a few trisalts of antimony, of being derived from their respective acids by a substitution, not of netallic oxide for basic hydrogen, which metallic oxide is transferable und to another, throughout the entire series of double decompositions lts are liable. There is accordingly no hexchloride UCl^6 or hexnitrate nly an oxychloride UO^2Cl^2 and oxynitrate $UO^2(NO^3)^2$. The oxychloride stalline, readily fusible, but difficultly volatilisable mass. The nitrate emon-yellow prisms decomposible by heat, and yielding in succession a uranic oxide, uranoso-uranic oxide. Both salts are soluble in water, yellow fluorescent solutions. These are converted into uranous solu- retted hydrogen, with separation of sulphur, and are otherwise very . They give a dark brown precipitate with sulphide of ammonium; ystallisable double compounds with excess of alkaline carbonate, the having the formula $2K^2CO^3.(U^2O^2)''CO^3$; and yield precipitates of , $K^2O.2UO^3$, for instance, with caustic alkalis.

the symbols of the elements are arranged in the order of the atomic only in the case of tellurium, the symbol of which is placed imme- istead of below that of iodine; its atomic weight has perhaps been estimated. Departing from the order of numerical seriation in this it is remarkable with what facility the symbols of the elements may parallel lines and columns, corresponding with a natural classification themselves into analogous groups and series. Indeed a study of the f elements at present known would seem to indicate that they are one ed with each other by a certain community of relationship, of which the dation and parallelism in properties and atomic weights, of the alkali and earth-alkali, and of the halogen and oxygen families of only the most prominent examples.

econd line of the table as an illustration, it is observable that the first mbolised therein are distinguished from all the others by the property chloride only and that a dichloride; further that the metals in the ed columns of this line, namely magnesium 24, zinc 65 and cadmium nent in the air, volatilisable in the direct, and basylous in the inverse tomic weights, and are otherwise specially associated with one another, larly associated metals in the first three alternate or even-numbered y calcium 40, strontium 87·5 and barium 137, are quickly oxidisable in ctically non-volatile, and are basylous in the direct instead of in the their atomic weights; and similarly on the other lines of the table, e divisible into sub-groups according to their odd and even positions.

he relationship of the elements placed in the same line, the relationship in the same column is of a different kind. Taking the third and s by way of illustration, it is observable that the consecutive elements have closely consecutive atomic numbers; that the element on the a monochloride, that on the second line a dichloride, that on the third

S. *Aerolites. Uranolites.* This name includes, not only those hich are known to have fallen on the earth's surface from the t likewise a great number of others, which, though their origin is n, yet agree so closely with known meteorites in mineralogical and on, as to justify the conclusion that they are also of meteoric origin. alyses which have been made of meteorites, both the older ones by oth, and Vauquelin, and those of more recent date by Berzelius monstrated in them the presence of about 18 elementary bodies, all of r in terrestrial minerals, viz. aluminium, calcium, carbon, chromium, n, magnesium, manganese, nickel, oxygen, phosphorus, potassium, itanium, tin, and perhaps also in some cases, antimony, arsenic, and lead.

livided into two classes, distinguished as Meteoric Iron, and es. Meteoric iron consists chiefly of metallic iron alloyed with oxidised compound, and has in general the characters of ordinary e stones are mixtures of several minerals, chiefly silicates (felspar, ch also play an important part in terrestrial minerals.

owever merely artificial, inasmuch as many meteorites are mixtures th masses of meteoric stone, or with one or more of the minerals ic stones. If the metallic portion predominates, the meteorite is iron, as for example the so-called Pallas meteorite, found at Kras- or that of Atacama, both of which contain larger or smaller masses in cavities in the iron. If, on the other hand, the earthy portion minates in amount, the meteorite is called a meteoric stone, although grains of meteoric iron diffused through the mass may give it an ifferent from that of meteoric stones consisting wholly of earthy e stones containing metallic iron are much more numerous than olly of earthy minerals.

1. Meteoric Iron.

oric iron is always a mixture, the constituents being sometimes evealing themselves only to chemical investigation. The chief part of f iron alloyed with nickel, and perhaps always with a small quantity dmixture of nickel is usually regarded as a proof of the meteoric masses of metallic iron found on or a little below the surface of tual fall has not been observed. The amount of iron in meteoric from about 80 to 95 per cent.; the nickel from 6 to 10 per cent.

lphide of iron is visibly disseminated through the mass, sometimes er large cylindrical grains. This sulphide is often regarded as Fe^3S^2 (p. 401), which does indeed occur in some meteorites; but

Contains, according to Berzelius, magnetic iron ore, and silicates, of
ent. consist of a silicate decomposible by nitro-muriatic acid, and
sition of olivin (containing 1 at. iron to 2 at. magnesium), with
in, and alkali-metals, and 6·45 of a silicate of aluminium, iron,
lcium, the composition of which has not been determined; also a
hrome-iron.
le, South Carolina. March 1843. A very peculiar stone, consisting
of a white mineral partly crystallised and apparently monoclinic.
3·116 (Shepard); 3·039 (Waltershausen). Melts before the
e enamel. Contains also small quantities of magnetic pyrites and
lded in the mass. An analysis of the white mineral by Walters-
per cent. silica, 1·48 alumina, 1·70 ferric oxide, 27·11 magnesia,
7 water, whence it appears to consist essentially of chladnite,

aps identical with this, obtained from a mass of iron said to be from
of Grimma, was described 30 years ago by Stromeyer.
ew Hampshire. White porous mass, which melts on the edges before
ring the flame yellow. Contains, according to B. Silliman, 84·97 per
nd 2·22 soda, an unusual composition which may be represented by
$4SiO^2 + 9Mg^2O.4SiO^2$; considered doubtful by Rammelsberg.
Cape Colony. October 13, 1838. Soft black mass with a few
nits a bituminous odour when heated, and contains a resinous or
oluble in alcohol, which easily melts and chars. When ignited in
r, even after being freed from the resinous substance, it burns and
y of carbonic anhydride equivalent to 1·6 per cent. carbon. It there-
on, to which in fact its black colour is due. It contains water, even
0°. It also yields when heated a small quantity of sublimate con-
of ammonium. It acts but slightly on the magnetic needle, and
but little magnetic iron. It contains 3·8 per cent. sulphur, but does
lphur when heated, or evolve sulphydric acid gas when treated with
hence it cannot contain either iron pyrites, magnetic pyrites, or
Wöhler considers the sulphur as belonging to a sulphide of nickel
$^2S^3$, which requires 1·3 nickel to 2·5 iron, quantities agreeing with
alysis. From an analysis by Harris, made under Wöhler's direction,
cludes that the stone contains 6·94 per cent. nickel-iron-sulphide,
stone, 84·32 olivin, 5·46 undecomposible silicates, and 1·92 carbon
atters.
Debreczin, in Hungary. April 15, 1857. Dark grey, earthy ground-
white and greenish grains, resembling olivin, also numerous black
ttle, hollow within, and consisting of a colourless crystalline mineral
al. The ground-mass exhibits nothing metallic, but yields a small
o the magnet. Its composition, according to Wöhler's analysis, is
the preceding, with addition of 3·55 per cent. magnetic pyrites.
xygen gas, it gives off carbonic anhydride, together with a little water
ublimate. Alcohol extracts from it a white carboniferous substance
n and scheererite, very fusible, partly volatile, partly decomposed by

LUMINIC. AlC^3H^9, or $AlMe^3$. (Buckton and Odling, Proc.
) When mercuric methide and excess of aluminium clippings con-
ibes are heated for some hours in a water-bath, the mercury com-
aluminium, thus:

$$3HgMe^2 + Al^2 = 2AlMe^3 + Hg^3.$$

ut of contact with air, the aluminic methide is obtained as a colour-
which at a little above 0° congeals into a transparent crystalline
adily at 130°. At and above 220° its vapour-density was found to
ical density calculated for the formulæ $AlMe^3$ being 2·5. But its
r expansion, increases rapidly with every decrease of temperature, so
it becomes 3·96 or 4·1; while at its boiling point 130°, it is as high as
nates to the theoretical density 5·0 calculated for the formula Al^2Me^6.
takes fire spontaneously on exposure to air, burning with a very
roducing abundant flocculi of alumina discoloured by soot. By a
to dry air, it absorbs oxygen, with production of a body apparently
dioxymethide (p. 986). It is decomposed by water with explosive
with iodine to form iodo-derivatives and iodide of methyl.
ide, AlE^3, is made by a precisely similar process, using mercuric
mercuric methide. It is a colourless liquid which does not
It boils at 194°, and its vapour-density taken at 234° was found to
al density calculated for the formula $AlEt^3$ being 3·9. The excess
over the calculated density was obviously due to some unavoidable
bstance examined. Aluminic ethide takes fire spontaneously on ex-
its other chemical properties closely resembles the methyl compound.
im. Phys. [3] lviii. 5) observed that aluminium was attacked by the
nd ethyl at 100°—130°, and that the crude ethylated product reacted

substances, resembling the ulmic compounds, prod
thylic alcohol on chloroform. The immediate pro
thulmic acid and its sodium-salt, together with
hydrogen, and chloride of sodium:

$$4CHCl^3 + 6CH^4O + Na^{11} = C^5H^7ClO^2 + C^5H^6Na$$

Chloro-form. | Methylic alcohol. | Chlorome-thulmic acid. | Chlorome-mate of s-dium.

Chloromethulmic acid is black, semifluid, h
alcohol.

By boiling with *potash*, it is resolved into met
methulmic acid, $C^5H^8O^4$:

$$2C^5H^7ClO^2 + 2KHO = 2KCl +$$

Methulmic acid is dark yellow, soluble in ethe
by *bromine* into black, semi-fluid dibromometh
treated with *sulphuric acid* at 60°, is resolved into
of hypomethulmene, $C^4H^6Br^2$, a yellow-brow

Dioxymethulmic acid, $C^5H^8O^4$, is black,
soluble in alcohol.

Chlorethulmic acid, $C^6H^9ClO^2$, and chlo
produced in like manner by treating chloroform
cohol, and from these may be obtained derivatives
in composition to the methyl-compounds above de
$C^6H^8Br^2O^2$, heated to 60° with *sulphuric acid*, is
dibromide of methulmene, $C^5H^8Br^2$, a brown
alcohol, but soluble in ether. It is converted by
nitrobromide of methulmene, $C^5H^8(NO^2)Br$
potash-lye into bromomethulmene, C^5H^7Br, a
and in alcohol, soluble in ether.

Compounds similar to the preceding are said t
with sodium in conjunction with aldehydes, aceto
form is replaced by certain other compounds, esp
must be observed, however, that the composition
above mentioned has not been established by a
must be considered doubtful, especially as none
crystalline form.

METHYL. CH^3; often denoted by the sho
$C^2H^6 = Me^2$. The first of the series of alcohol

RIDE OF. *Boric Methide. Bormethyl.* $B(CH^3)^3$. (Frankland, p. 176; Chem. Soc. Qu. J. xv. 373.)—A gaseous compound homolo- ethyl (ii. 525), produced by the action of zinc-methyl on borate of

$$(H^5O)^3 + 3Zn''(CH^3)^2 = 2B(CH^3)^3 + 3Zn''(C^2H^5O)^2.$$

thylic ate. — Zinc-methyl. — Boric methide. — Ethylate of zinc.

bout two ounces of boric ether were mixed in a small flask with
eir own bulk of an ethereal solution of zinc-methyl, of such strength
usly inflammable in a high degree. The flask, loosely corked, was
vater, and allowed to stand for a couple of hours until the reaction
was then furnished with a bent tube passing through a cork, to
nto a second flask placed in a freezing mixture of ice and salt;
gas passed into a third containing about half an ounce of strong
ia. The air in the whole of the apparatus was now displaced by
lask containing the boric ether and zinc-methyl removed from the
slow evolution of gas immediately commenced, and was kept up at
by plunging the generating flask into cold water, to which heat was
d. The gas, in passing through the freezing mixture, deposited
the ether and zinc-methyl vapour with which it was contaminated;
e solution of ammonia, the boron-compound was instantaneously
her gases, if present, passed through the ammonia unacted upon,
e atmosphere. The solution of ammonia soon became covered with
er liquid, which increased in quantity until the stream of gas ceased
he ammonia-flask was now disconnected from the rest of the appara-
r the next operation. The residue in the generating flask solidified
s on cooling.
gaseous boron-compound from its combination with ammonia, the
fitted with a funnel-tube terminating beneath the surface of the
delivery tube, the latter leading to a Liebig's potash-apparatus
ntrated sulphuric acid; finally, the opposite extremity of the latter
ected with a mercurial gas-holder. To prevent dangerous explosions,
of the spontaneously inflammable gas from its ammonia-compound,
-spaces of the apparatus were filled with nitrogen. Everything being
e sulphuric acid was gradually poured into the ammonia-flask through
contents of the flask being frequently agitated. No gas was evolved
ammonia was saturated; then, however, it was given off abundantly,
of a few drops of sulphuric acid, from time to time, through the
to keep up a convenient current. The gas was allowed to pass
depressed mercurial gas-holder until a sample of it proved, by its
ammonia, that all nitrogen had been swept from the apparatus.

OMIDE OF. CH^3Br. *Methyl-hydrobromic ether. Hydrobromate* ierre, J. Pharm. [3] xiii. 156; Jahresb. 1847–48, p. 672.—Pharm. xlvi. 44.)—Prepared by mixing, at a temperature of 5° or 6°, , 200 of methylic alcohol, and 7 of phosphorus. The temperature eously, and the phosphorus melts. The mixture must be cooled, cautiously distilled. As thus obtained, it is a colourless liquid, of ghtly alliaceous odour; boils at 13° under a pressure of 0·759 met. violently on cacodyl, forming bromide of cacodyl, and bromide of um (Cahours, Jahresb. 1861, p. 554):

$$(CH^3)^2 + 2CH^3Br = As(CH^3)^2Br + As(CH^3)^4Br.$$

he composition of bromide of methyl, is evolved on gently heating f cacodyl. It has a density of 3·253 (Bunsen, *Gasometry*, p. 121), 4; a faint ethereal odour, and condenses at −17° into a thin, transquid. It burns with a yellowish flame when mixed with air, and with oxygen on the application of flame.

HLORIDE OF. CH^3Cl. *Methyl-hydrochloric ether. Hydro-ne.* (Dumas and Peligot (1835), Ann. Ch. Phys. lxi. 193).—Prea mixture of 2 pts. chloride of sodium, 1 pt. of wood-spirit, and phuric acid. Chloride of methyl then passes over as a gas, which may water; it is, however, contaminated with wood-spirit, sulphurous lride of methyl.

yl is a colourless gas, having an ethereal odour and saccharine taste. 36. It does not condense at −18°. Water dissolves 2·8 times its at 16°.

hyl burns with a white flame, green at the edges, producing water, and carbonic anhydride. Passed through a red-hot tube, it is ht deposition of charcoal, into a mixture of methylene and hydro-l = CH^2 + HCl (Dumas and Peligot). According to Perrot ci. 375), it deposits charcoal, and yields hydrochloric acid, marshonic oxide, naphthalene, and a substance which unites with bromine compound, melting at 40° and boiling at 220°. When passed over it yields formate and chloride of potassium, together with hydrogen

$$CH^3Cl + 2KHO = CHKO^2 + KCl + 2H^2.$$

phosphide of calcium at 200° or 300°, it yields a number of phos-, some of which appear to be organic bases. (P. Thenard.)

ne same composition and physical properties as the preceding was n, by the action of heat on basic perchloride of cacodyl. Kolbe p (Ann. Ch. Pharm. lxxvi. 37) also obtained a gas of the same ving a mixture of equal volumes of marsh-gas and chlorine exposed ht. Gerhardt (*Traité*, i. 566) regarded the first only of these the two latter as $CH^2Cl.H$.

Ch. Pharm. cvii. 181) finds that the gas produced from basic per-l, exhibits the same degree of absorbability in water as that ing wood-spirit with salt and sulphuric acid, the coefficient of h these gases being 5·034 at 7°; 4·172 at 14°; 3·462 at 20°; and loreover, the gas obtained by either of these methods forms a when passed into water cooled below 6°. On the contrary, the gas ction of chlorine on marsh-gas does not form a crystalline hydrate, aller coefficient of absorption in water (0·08 at 14°). Hence Baeyer gas produced by the decomposition of basic perchloride of cacodyl hloride of methyl, but that the gas resulting from the action of gas is a substitution product isomeric but not identical therewith. helot, on the other hand, the last-mentioned gas is really chloride y be converted into methylic alcohol by the action of potash.

hyl is not attacked by chlorine in diffused daylight, but when ct rays of the sun, it yields successively the three compounds—

URAMINE. $C^2H^7N^3$. (Dessaignes, Compt. rend. xxxviii. 839.)— d by heating an aqueous solution of creatine or creatinine with mer- arbonic anhydride is then evolved without a trace of ammonia; the oxide artly reduced; and oxalate of methyluramine is obtained in crystals:

$$\underset{\text{reatine.}}{C^4H^9N^3O^2} + O^3 = \underset{\substack{\text{Oxalate of Methyl-}\\\text{uramine.}}}{(C^2H^7N^3)^2.C^2H^2O^4} + 2CO^2 + H^2O$$

$$\underset{\text{Creatine.}}{2C^4H^7N^3O} + O^3 = (C^2H^7N^3)^2.C^2H^2O^4 + 2CO^2.$$

of oxide of mercury is too small, the crystals of oxalate of methyl- ixed with crystals of creatine; but when a sufficient quantity of is used, the oxalate of methylamine is obtained in large quantity and creatine. To separate it completely, the solution must be repeatedly cohol and evaporated. It may also be produced by treating creatine of lead and sulphuric acid; but this method does not yield so pure a preceding. (Dessaignes, Compt. rend. xli. 1258.)

der the microscope, fresh milk appears as a clear liquid in which the *-globules* are suspended. They vary considerably in size (diameter = 2" and 0·0018"), and rarely in fresh milk attain the diameter of 0·0038". ddition of reagents, they appear merely as globules of fat.

proved the existence of an external envelope; he added acetic acid to the d that the shapes of the globules were thereby distorted. Mitscherlich globules were not dissolved when milk was shaken up with ether, which en the case if they were a simple emulsion of fat; if, however, caustic potash f potassium, which dissolves the envelope, was previously added, the fat solved by ether. Lehmann also remarked that the surface of the ilk merely treated with ether, appeared less transparent, turbid, and f it had been coagulated; the ether took up the fat on the addition of sodium. Moleschott acted on the coagulum, obtained by adding lk, with acetic acid, and extracted the fat with ether; there remained n fat envelopes in the form of little vesicles, which he was able to fill eal solution of chlorophyll; they contained no fat. From this he not only istence of the fat envelopes, but concluded also that they are organised. *Physiol. Heilk.* xi. p. 696–708.)

nd of morphological elements, the so-called *granular bodies* (*corps lostrumkörperchen*), occurs in the colostrum (the milk secreted during r three days after parturition). They consist of irregular conglomerations fat-vesicles, united by an amorphous and somewhat granular substance. r = about 0·0111" (Henle), but varies between 0·0063" and 0·0232". ich more easily dissolved by ether than that of milk-globules. They are potash or by acetic acid; iodine-water imparts an intensely yellow m; hence they consist of very small globules of fat imbedded in an ubstance. They are found in human milk up to the third or fourth day th, sometimes, however, as late as 20 days after. Moleschott found in of cows, together with milk-globules, five different kinds of granular bules (*loc. cit.*).

olostrum is at first yellow, on the first and second day; it then becomes n the third or fourth day becomes white. According to G. Veit, in the olostrum to milk, the milk-globules (which cohere in the colostrum) lose and the largest (above 0·00166" in diameter) disappear, when a richer rmed, and albumin ceases to be present in the milk. The secretion of begins on the fourth day at the earliest, but generally between the sixth .

Constituents of Milk.

i. 810). Simon found 4·0 per cent. casein in human colostrum, and 2·15 e milk six days after delivery. Milk varies in composition at different ay. In the case of two cows fed with hay, oat-straw, beet-root, oil-cake, , the milk obtained in the morning (4 A.M.) contained 2·56 and 2·51 per nid-day, 2·23 and 2·38 respectively. In another case, the milk contained, , 2·24 and 2·25; at mid-day, 2·37 and 2·36; in the evening (7 P.M.), 2·70 cent. casein respectively (Struckmann and Bödeker). Heynsius portion of cow's milk richer in casein than the last portions. Accord- is and Becquerel, the amount of casein in human milk varies directly ntity yielded; in cow's milk, inversely as the quantity. The milk of ains about 0·3 per cent. more casein than that of blondes. Women of tion yield almost normal milk, while those of vigorous constitution yield casein. In *acute diseases*, out of 19 cases, the average percentage of 40 per cent. (3·291—5·671); and in 27 cases of *chronic diseases*, 3·257 1—3·989) (Vernois and Becquerel). The milk of nurses between rs old contains 5·574 per cent. casein and extractive matter; 20—25, ; 25—30, 3·653 per cent.; 30—35, 4·233 per cent.; 35—40, 4·207 per cent. ous substance has been met with in milk, and especially in colostrum, agulated by rennet, but is precipitated by boiling. This is supposed to G. Veit remarked that the colostrum of women, up to the third day coagulated entirely or in part on heating. It afterwards lost this pro- trate obtained from the acid colostrum of the cow, after adding chloride e no turbidity with acetic acid, but yielded a precipitate with tannin, nd by heat; on adding ammonia and boiling, an abundant precipitate t the liquid remained unchanged when treated in the same way with Hence albumin must have been present (Moleschott). Vernois and und, in the milk of the buffalo-cow and of the goat, 1·3 per cent. albumin. nd 0·5 per cent. albumin in cow's milk previously coagulated with acetic ecipitated by boiling; but if the milk was previously boiled and coagu- acid at 40° C., no turbidity was produced in the filtrate by acetic acid Albumin is also found in milk in inflammatory diseases of the mammary nen it contains blood and pus. Nevertheless, it must be remarked that pared a kind of casein from normal milk, which coagulated by heat; ilk sometimes becomes thick on heating, but returns to its previous state Dumas.)

t of human milk has not been examined qualitatively with any degree The butter of cow's milk has however been more particularly investi- milk-fat is a colourless or very pale yellow substance, solidifying at pon the temperature rises to 32°. It is soft and sticky above 18°. ·9 pts. of boiling alcohol of specific gravity 0·822. It readily becomes sure to the air, yielding volatile fatty acids, and then decidedly reddens y be completely saponified, and then yields, together with glycerin, mar- pric, caprylic, caproic, and butyric acids, or instead of the two last, Lerch), or, according to Heintz, oleïc and butic ($C^{28}H^{46}O$, melting-point tearic, palmitic, and myristic acids (Chevreul, *Sur les Corps gras*, is, Ann. Ch. Pharm. xlii. 46, &c.; Heintz, Ann. Ch. Pharm. lxxxviii. . Ann. xc. 137). Bromeis reckons the composition of butter according ies of acid found = 68 per cent. margarin, 30 per cent. elain, and liar butter fat; but the components of butter seem to vary considerably.

eral from Chile appears to be hedyphane mixed with a little vanadate

ACACIA GUM. See Gum (ii. 953).

IC ACID. Syn. with Catechu-tannic Acid (i. 817).

I SPIRITUS. Acetate of Ammonium (i. 13).

This term, in its widest sense, denotes any substance not formed organic life; in its more restricted and more usual sense, it signifies solid or liquid inorganic body, formed by natural processes, without art. Minerals understood in this sense, constitute the essential part t. It is usual, however, to include under the same general denomi-stances which are evidently the remains of organised beings, chiefly ived upon the earth in former ages, *e.g.* coal, lignite, amber, and the fossil resins and bitumens. Such bodies should perhaps in strict-ils, but they are more usually classed with minerals, and described n Mineralogy.

ACIDS are acids of inorganic origin, either existing ready formed s, or formed from inorganic materials by artificial processes. The plied to the stronger acids, sulphuric, nitric, phosphoric, hydro-

ALKALI. An old name of Soda. (See Alkali, i. 115.)

BLUE. A term sometimes applied to Prussian blue when mixed substances, such as clay, heavy spar, gypsum, &c., which give it a

CAOUTCHOUC. Syn. with Elaterite (ii. 374).

CHAMELEON. Manganate of potassium (p. 818).

GREEN. Scheele's green. (See Green Pigments, ii. 914.)

INDIGO. A term applied by Keller to the blue oxide of molyb-the reducing action of tin or stannous chloride on recently precipi-d. (See Molybdenum, p. 1036.)

KERMES. Amorphous Trisulphide of Antimony (i. 330).

OIL PITCH, RESIN. (See Petroleum.)

PURPLE. Gold-purple or Purple of Cassius (ii. 938).

TALLOW. Syn. with Hatchettin (p. 14).

TURPETHUM. Mercuric sulphate. (See Sulphates.)

WATERS. See Water.

YELLOW. A term sometimes applied to the yellow oxychlorides ments (p. 556).

MINETTE. An eruptive rock occurring in the Vosges, where it forms small veins chiefly in granite and syenite. It consists of mica (the characteristic constituent) varying in colour from brownish-black to greenish, and orthoclase imbedded in a felspathic ground-mass. It is usually fine-grained, often porphyroïdal, when the felspar crystals are well developed. The ground-mass frequently also contains greyish-green or dark green hornblende already far advanced in decomposition. The rock also contains quartz (in very small quantity), triclinic felspar, chlorite, calcspar, &c., often also crocidolite. A specimen from the Ballon d'Alsace, gave by analysis:

SiO^2.	Al^2O^3.	Mn^2O^3.	FeO^3.	CaO.	MgO.	K^2O.	Na^2O.*	H^2O.	CO^2.
56·96	12·95	0·65	7·58	4·63	6·62	4·35	2·22	1·44	1·94 = 99·34

(Delesse, Ann. Min. [5] x. 517; Jahresb. 1857, p. 705). A rock of similar constitution, from Mittershausen in the Odenwald, has been analysed by Bunsen (Jahresb 1861, p. 1068).

MINIUM. Red oxide of lead (p. 551).

MINJAC-TANKAWAN or **TINKAWAN.** A solid vegetable fat obtained from the fruit of a tree growing in Borneo and Sumatra. The principal portion of it, insoluble in cold alcohol, consists, like cacao-fat, of stearin, palmitin and olein; a smaller portion, soluble in cold alcohol, contains free stearic acid, palmitic acid, and traces of a volatile fatty acid. (E. Ruge, Jahresb. 1862, p. 506.)

MIRABELLES. See FRUIT (ii. 714).

MIRABILITE. Syn. with Glauber salt. (See SULPHATES.)

MISENITE. Acid sulphate of potassium, $KHSO^4$, occurring in white silky fibres in a hot tufa cavern near Misene. (Scacchi, Mem. Geol. sulla Campania, 1849, p. 98.)

MISPICKEL. $Fe^2As^2S^2$, *Arsenical pyrites, Arsenopyrite, Danaite, Plisian, Fer arsénical, prismatischer Arsenikkies.*—This mineral occurs in trimetric crystals, in which the ratio of the axes $a : b : c = 0{\cdot}676 : 1 : 1{\cdot}189$. Angle $\infty P : \infty P = 68° 7'$; $\frac{1}{4}P\infty : \frac{1}{4}P\infty$ in the basal principal section $= 34° 34'$. Ordinary combination $\infty P . \frac{1}{4}P\infty$. Cleavage rather distinct, parallel to ∞P. Occurs almost columnar, compact granular, or impalpable. Hardness = 5·5 to 6. Specific gravity = 6 to 6·4. Lustre metallic. Colour silver-white inclining to steel-grey. Streak dark greyish-black. Fracture uneven. Brittle. Heated in a tube, it first yields a red or brown sublimate of sulphide of arsenic, then a black sublimate of metallic arsenic. On charcoal before the blowpipe, it melts to a black magnetic bead, which sometimes exhibits the reactions of cobalt as well as those of iron. According to Berthier, when heated in a closed crucible, it gives off half its sulphur, and a fourth of its arsenic. Nitric acid decomposes it, with separation of sulphur and arsenious acid; nitro-muriatic acid, with separation of sulphur alone, which may be completely dissolved by prolonged digestion.

Native titanate of iron. (See TITANIUM.)

... This term, in its strict chemical sense, denotes the smallest quantity body that can take part in any chemical reaction. Thus, as explained TOMIC WEIGHTS (i. 457–469), the molecule of water is assumed to be not $HO = 9$, because, in the great majority of cases, 18 pts. by weight smallest quantity of water that can be taken up by, or eliminated from, ments concerned in a reaction. For a similar reason, the molecule of med to be $NH^3 = 17$, and not any multiple or submultiple thereof. Chem. Soc. Qu. J. xi. 107.)

all the considerations by which the molecular weights of bodies are de- be to repeat what has already been treated in some detail in other ork, especially that above referred to (see also CLASSIFICATION, i. 1007). suffice to point out in this place that, among the purely chemical con- h enter into the determination of this point, a prominent place must he manner in which the elements of a compound are replaced by other or compound. Thus, in the four typical molecules,

$$HCl, \quad H^2O, \quad H^3N, \quad H^4C,$$

the first, viz. hydrochloric acid, must be either wholly replaced or not at water, either the half or the whole of the hydrogen may be thus re- ther fraction; and in ammonia, the substitution takes place by thirds; s, by fourths. Again, sulphuric acid is regarded as dibasic, and repre- ; phosphoric acid as tribasic, and denoted by H^3PO^4; tartaric acid as $.C^4H^2O^6$, for similar reasons.

iderations likewise enter largely into the determination of molecular in compound gases and all compounds whose specific gravities can be he state of vapour, the molecule is assumed to be so constituted that ble of the specific gravity, that is to say, of the weight of a unit-volume This assumption cannot at present be said to rest on any physical found to be true in numerous cases in which the weight of the molecule spendently of it by purely chemical considerations; and hence it is ex- in which such verification cannot be obtained. Other physical con- h enter into the determination of molecular weights are specific heat, morphism, &c. (See ATOMIC WEIGHTS, i. 466–473; HEAT, iii. 30–40 MORPHISM, iii. 423–432.)

ecule, as applied to elements, must be understood in a somewhat rom that which it bears when applied to compounds. The smallest lementary body that can enter into a reaction is called, not a molecule, nd the molecule of an element is the smallest quantity, or group of exist in the free state. Many considerations lead us to suppose that in cases, this group consists of two elementary atoms, the molecule of xample, being HH. (See ATOMIC WEIGHTS, i. 466; and CHEMICAL,) There are also certain compound radicles, viz. the alcohol-radicles c., whose molecules in the free state are generally supposed to be the by which they enter into combination; *e.g.*, free methyl = $CH^3.CH^3$; tigations on the relations between these radicles and their hydrides ave thrown considerable doubt on the existence of these particular ules.

...UM. *Symbol*, Mo. *Atomic Weight*, 92.—A metal occurring in a sulphide (*molybdenite*), and as molybdate of lead (*wulfenite*). The was first distinguished from plumbago, which it much resembles, by 8; the metal was first prepared from the trioxide by Hjelm in 1782. plete investigations of the properties and combinations of this metal e by Berzelius (Pogg. Ann. iv. 153; vi. 361, 369; vii. 261); Struve (J. pr. Chem. xliv. 257; Jahresb. 1847–48, p. 408); Struve

omide or *Molybdous bromide*, $Mo''Br^2$, is produced, as just stated, by nation of its elements, also by heating the tribromide. It is a non-volatile, reddish-yellow body, which is not perceptibly attacked by hydrochloric, boiling nitromuriatic acid, but dissolves easily and completely when heated austic alkalis, forming a yellow solution containing molybdous oxybromide·

$$3MoBr^2 + 2KHO = 2KBr + H^2O + Mo^2Br^4O.$$

solutions of caustic alkalis decompose the bromide completely, with pre- a black hydrated oxide.

solution above mentioned, when exposed to the air, gradually deposits golden yellow crystals of a hydrated molybdous oxybromide,

^2O; but when neutralised with an oxygen-acid, it yields a dark yellow, granular precipitate of the same oxybromide with a smaller quantity of

$^4O.3H^2O$. The oxybromide dissolves with yellow colour in alkalis and in oxygen-acids, and from the acid solutions thus obtained, the bromine is not by silver salts.—The solution of the oxybromide in dilute aqueous alkalis *ydrobromic, hydrochloric*, or *hydriodic acid*, a yellow precipitate, insoluble

soluble in alkalis, and consisting of $Mo^2Br^4.3H^2O$, $Mo^2Br^4Cl^2.3H^2O$ or

^2O.—Blomstrand regards all these compounds as containing the diatomic *omolybdenum*, $MoBr^4$, *e.g.*, the oxybromide, $(MoBr^4)''O$, the chlorobromide, &c. (See page 1030.)

romide, $Mo''Br^3$, or *Molybdoso-molybdic bromide*, $MoBr^2.MoBr^4$, is above mentioned, by direct combination, or with greater facility by passing our over a heated mixture of molybdic oxide and charcoal. It is sometimes eparate crystals, but more frequently in blackish-green masses consisting apillary, interlaced needles. It is difficult to sublime, and at a bright red ed into the dibromide and free bromine. It is not even wetted by water, ked by boiling hydrochloric acid or by cold dilute nitric acid. Dilute pon it slowly, and at the boiling heat decompose it completely, with black molybdic hydrate.

abromide or *Molybdic bromide*, $Mo^{IV}Br^4$, formed also by direct com- 1028), is fusible and volatile, forming a brown-red vapour; it deliquesces a black liquid; and forms with water a yellow-brown solution, from which down molybdic hydrate of a rusty yellow colour. It is easily resolved by dibromide and free bromine, the temperatures at which it is formed and being very close together.

romide, $Mo^{VI}Br^6$, has not been obtained, but the corresponding *oxybro-* Br^2O^2, is produced by passing bromine-vapour over heated molybdic oxide, heating molybdic trioxide with boric, or phosphoric anhydride, and fusing d mass with bromide of potassium, *e.g.*:

$$MoO^3 + B^2O^3 + 2KBr = 2KBO^2 + MoBr^2O^2.$$

y sublimed, it forms indistinct crystalline scales; but by slow sublimation tained in more distinctly developed crystalline plates of yellow-red colour re, which deliquesce in contact with the air, and form a colourless solution

DENUM, CHLORIDES OF. Molybdenum forms three chlorides, the bromides. The tri-chloride and tetrachloride were first prepared by ho also obtained the dichloride in solution; these compounds have been xamined by Blomstrand, who has also obtained the anhydrous dichloride xychlorides.

de or *Molybdous Chloride*, $Mo''Cl^2$.—This compound is formed, the other chlorides, by passing chlorine-gas over heated molybdenum. It ared, though not in a state of purity, by exposing the trichloride to a at in an atmosphere of carbonic anhydride, or other gas which does not act y heating metallic molybdenum with calomel; also, though in very small passing chlorine-gas largely diluted with carbonic anhydride over mode- molybdenum; it is likewise formed in small quantity, together with the , by passing chlorine over a heated mixture of molybdic oxide and char- e temperature is very high. (Blomstrand.)

s chloride is obtained, in solution, by saturating hydrochloric acid with mo- rate. The dark-brown solution yields on evaporation a black mass which lmost entirely in water, but on evaporation in vacuo, gives off hydrochloric ter, and is converted into a black pulverulent oxychloride. (Berzelius.)

lution is red, and yields by evaporation in contact with the air, a
which is red by transmitted, brown by reflected light. It decomposes
rature, giving off hydriodic acid and leaving molybdic oxide. The
ontaneous evaporation redissolves in water. (Berzelius.)

UM, IODOBROMIDE and **IODOCHLORIDE OF.** $Mo^4Cl^4I^2$.—These compounds are obtained by the action of hydriodic
s oxybromide and oxychloride respectively (pp. 1029, 1030).

UM, NITRIDES and **AMIDES OF.** (Tuttle, Ann. Ch. Pharm.
b, Pogg. Ann. ci. 605; Jahresb. 1857, p. 194.)—These compounds,
been very exactly investigated, are obtained by passing ammonia-gas
rioxide, or the chlorides of molybdenum, at high temperatures.
g molybdic chloride in ammonia-gas till the resulting chloride of
olatilised, obtained a black sintered mass containing 82·8 per cent.
bably consisting of $2MoN.MoH^4N^2$.

so obtained compounds of similar constitution by the action of dry
nolybdic chloride. The action takes place even at ordinary tempera-
nded with sufficient evolution of heat to partially fuse the mass and
of ammonium. On subsequently applying a gentle heat, the product
nd soon solidifies to a black tumefied mass, exhibiting stellate groups
als on the colder parts; when completely freed from sal-ammoniac by
th water, and then dried in a vacuum over oil of vitriol, it exhibited a
ssible by the formula $Mo^3H^4N^{10}$ or $4MoN^2.MoN^2H^4$. This compound
oxygen gas, with formation of water, and gives off ammonia when
en gas, or fused with hydrate of potassium. A compound resembling
external appearance, but consisting of $8MoN.MoH^4N^2$, was obtained

er oxidises nor dissolves it.

hydrate is obtained by precipitating a solution of molybdic chloride or
ic salt with ammonia, which must be added in excess, as otherwise a
sult will be formed, especially with the chloride. The hydrate itself is
t soluble in pure water, so that, in very dilute solutions, ammonia does not
ipitate until sal-ammoniac is added. For the same reason, the washing
arried too far, and is best finished with water containing alcohol. The
ate may be pressed between paper and dried in a vacuum. It has a
olour, just like that of ferric hydrate precipitated by ammonia. When
e moist state to the air on filtering paper, it acquires a darker colour and
ce, and begins to deliquesce, passing into a higher and much more soluble
solves, as already observed, in a large quantity of water, forming a dark
which gelatinises when kept for three or four weeks in a closed vessel,
s, a property likewise retained by the hydrate precipitated from it by
, and has a somewhat astringent taste, with metallic after-taste. This
n left to evaporate spontaneously, first gelatinises and then dries up to a
nearly black mass, green and blue on the edges, which is no longer
ter. The hydrate is insoluble in caustic potash, but dissolves in aqueous
ate of potassium, and more easily in the acid carbonate, from which solu-
ially precipitated on boiling. It dissolves also in carbonate of ammo-
completely precipitated therefrom by boiling; the precipitate is denser
ter yellow colour than that obtained with caustic ammonia, but dissolves,
, when washed with water. A solution of molybdic oxide in an alkaline
onverted by atmospheric oxidation into a molybdate of the alkali-metal.
ydrate dissolves in *acids*, forming the molybdic salts. These salts may
ned by digesting an excess of metallic molybdenum with the acid in
e dissolved, and adding nitric acid drop by drop till the other acid is
h molybdic oxide; or by digesting an excess of molybdenum with
hydride, and the acid which is required to dissolve the resulting
le—hydrochloric acid, for example—till the blue colour first produced
ddish-brown; or lastly, by digesting molybdic anhydride with copper and
h in that case dissolves cupric and molybdic oxides together. The
s, in the anhydrous state, are almost black, but when hydrated they are
d reddish-brown solutions in water. They have a rough, somewhat
d subsequently metallic taste. Their solutions when heated in contact
have a tendency to become blue by oxidation. [For their behaviour with
p. 1039.]

s intermediate between the di- and tri-oxides will be described as
ybdates (p. 1039).

Molybdic Anhydride, Anhydrous Molybdic acid, MoO^3.—This oxide
as molybdic ochre or molybdin, forming an earthy coating on the
de, sometimes also independently; at Altenberg in Saxony it occurs in
ns of 136° 48′ (Breithaupt, Jahresb. 1858, p. 683). It may be formed
exposing molybdenum or its lower oxides, or molybdic sulphide, to long-
t in contact with the air, by fusing the same substances with nitre, or by
etal or its oxides in an atmosphere of aqueous vapour, or with hydrate of

a. From *Molybdic Sulphide.*—The precipitated sulphide, or the native
pulverised, is roasted, with continued stirring, in an open crucible placed
position, so that the air may easily play upon its surface. The native
ever, generally contains alumina, oxide of copper, and phosphoric acid,
of which from the product is very troublesome. Hence it is better to
ral in lumps in an open glass tube, through which a stream of air is
aspirator; the trioxide then sublimes in crystals in a state of perfect
hler, Ann. Ch. Pharm. c. 376.)

tive *Molybdate of lead.*—The mineral finely pounded and freed from car-
e, iron, and calcium, by digestion in dilute hydrochloric acid, and thoroughly
cantation, is heated with 1½ pt. strong sulphuric acid, with constant stir-
ulphuric acid begins to evaporate. It is then allowed to cool, a considerable
ater is added, and the insoluble sulphate of lead is filtered off. The
ed with nitric acid and evaporated, with constant stirring, in a porcelain
acid begins to evaporate; the molybdic anhydride then separates as a
, which may be freed from phosphoric acid by washing with water,
last with a few drops of nitric acid.—Or the mineral, after treatment with
hloric acid, may be evaporated to dryness with strong hydrochloric acid,

itrate. The solution of molybdic trioxide in nitric acid is reddish-
ply acid and subsequently bitter, metallic, astringent taste, and gives
nen evaporated.

hosphate or *Phosphomolybdic Acid.* Molybdic trioxide digested while
a small quantity of aqueous phosphoric acid, yields a lemon-yellow
water (Berzelius). With a larger proportion of phosphoric acid,
lissolves on the application of heat, forming a colourless liquid, which
ation, a tenacious, uncrystallisable, transparent mass, having a very
very soluble in water and in alcohol. The alcoholic solution is yellow,
n evaporation, and leaves a brown, opaque residue, which redissolves
g a blue solution. (Berzelius; see also Svanberg and Struve,
. lxviii. 209, 293.)

ecipitate formed on adding molybdate of ammonium to the solution of
nate (p. 1032) appears to vary in composition according to the circum-
rmation; at all events the formulæ (all very complicated) assigned to
emists do not agree with one another (see Nutzinger, Jahresb. 1855,
ohn, *ibid.* 1856. p. 375.—Eggertz, *ibid.* 1860, p. 620).—[For the
g phosphomolybdic as a test for the alkaloïds, see i. 127.]

ulphate. By boiling dilute sulphuric acid with an excess of molybdic
l, milky liquid is obtained, which gelatinises on cooling, and deposits
s of a basic compound, sparingly soluble in water but not in alcohol,
colours it green. (Berzelius.)

molybdic trioxide (not in excess) in dilute sulphuric acid has a light
nd dries up to a lemon-yellow crystalline mass, which deliquesces in
ly partially soluble in water (Berzelius). According to Ander-
esb. xxiii. 161), the solution of molybdic acid in sulphuric acid does
s on evaporation; but when molybdate of barium is decomposed by
sulphuric acid, and the clear solution evaporated over oil of vitriol,
ned.

artrate. The solution of molybdic trioxide in aqueous tartaric acid,
ation a blue non-crystalline mass, perfectly soluble in water and in
ng solution of acid tartrate of potassium easily dissolves molybdic tri-
ignition. The solution dries up to a gummy mass of *potassio-per-*
. (Berzelius.)

es, forming the Molybdates. Molybdic trioxide exhibits with most
he characters of an anhydrous acid, or anhydride, forming neutral
ontaining $R^2O.MoO^3$ or R^2MoO^4; acid and double molybdates,
epresented by the general formula $R^{2n}Mo^nO^{4n}$, the molecule R^{2n} being
or more metals, including hydrogen; and anhydro-molybdates,
he general formula $R^{2n}Mo^nO^{4n}.mMoO^3$, the letters m and n represent-
ers. The neutral molybdates of the alkali-metals are easily soluble
e obtained by digesting molybdic anhydride with the aqueous alkalis
nates. They are decomposed by the stronger acids, with precipitation
oluble acid salt, or of molybdic anhydride. Their behaviour with other
n already described (p. 1032). The molybdates of the other metals are
e obtained by precipitation. They are colourless unless they contain

f Lead. $PbO.MoO^3 = Pb''MoO^4$. This salt occurs native as *Wulfad ore* (*Gelbbleierz*) in modified square tables and octahedrons belonging ic system, the most frequent forms being P and P . oP. Length of 1·574. Angle P : P in the terminal edges = 99° 40′; in the lateral Cleavage indistinct parallel to P. It occurs also granularly massive, ly coherent. Hardness = 2·75 to 3. Specific gravity = 6·3 to 6·9. adamantine. Colour wax-yellow passing into orange-yellow, also reen, yellowish-grey, greyish-white and brown. Streak white. Subbtranslucent. Fracture subconchoïdal. Brittle. When heated, it gly, and assumes a darker colour, disappearing however on cooling, ow mass. When fused on charcoal before the blowpipe, it sinks into ng globules of lead, the charcoal at the same time becoming impregdenum and molybdide of lead. It dissolves easily in *borax* and in xhibiting the reactions of molybdenum already mentioned (p. 1032). *nitric acid*, with separation of yellowish-white permolybdic nitrate, g *hydrochloric acid* dissolves it, forming a green solution, together ead, which separates more completely on addition of alcohol. It distic *potash*.

ad occurs, with other lead ores, in veins of limestone, at Schwarzend Windish-Kappel, in Carinthia; it is also found at Retzbanya, in Moldawa in the Bannat, where the crystals are red, and bear co nce to chromate of lead; in small quantities also at the Southampton chusetts, and in fine reddish orange crystals, containing a trace of Wheatley's lead mine near Phœnixville, Pennsylvania. The specimens localities are nearly pure, the proportion of molybdic anhydride varying from 37·65 to 40·5 per cent., and that of lead-oxide from ont., while the formula $PbO.MoO^3$ requires 38·5 per cent. MoO^3 and Bleiberg mineral contains a small quantity of vanadium.

ad is formed artificially by precipitating nitrate of lead with neutral monium; also, according to Schulze, by fusing 2 pts. molybdate of s. chloride of lead and 4 pts. common salt. As thus prepared, it ite when pure, yellow if they contain a little phosphoric acid. Mixproportions, of molybdate of sodium, chromate of potassium, chloride on salt, yield crystallised salts, which, when they contain not more chromate of lead, are quadratic like those of pure molybdate of lead, ed colour; with from 42 to 90 per cent. chromate of lead, they are llow.

lead from Pampluna, in South America, was found by Boussing-Phys. [3] xlv. 325) to contain 73·8 per cent. PbO, 10·0 MoO^3, 2·9 P^2O^5, 1·2 Cr^2O^3, 1·7 FeO^3, 2·2 Al^2O^3 and 3·7 quartz (= 98·1); he sic salt, $3PbO.MoO^3$ or $Pb''MoO^4.2Pb''O$.

f Magnesium, $Mg''MoO^4.5H^2O$, is obtained in distinct crystals ic acid and *magnesia alba* with water, and evaporating the filtrate; ater at 100°. (Struve.)

Manganese is obtained as a heavy, white, crystalline powder, $O^4.H^2O$, by treating carbonate of manganese with trimolybdate of m; it gives off its water above 100°, dissolves sparingly in boiling oiled for some time with the acid molybdate of potassium or sodium, (Struve). Schultze, by fusing 1 pt. molybdate of sodium with chloride, and 2 pts. common salt, obtained the anhydrous salt ge dingy yellow crystals having the aspect of bitter spar, and apmicroscope as small monoclinic [?] tablets. Together with this salt med large red-brown laminæ of indeterminate form.

potassio-manganic molybdates are prepared by boiling the acid molybn and potassium with manganic hydrate (pp. 1037, 1040).

of Mercury. On adding mercurous nitrate to a solution of tassium, a yellowish-white flocculent precipitate is formed, which, if ted on a filter, and washed till the wash-water leaves no residue d ignition, consists of *mercurous dimolybdate* or *anhydro-molybdate*, $Hg.MoO^4.MoO^3$. It is yellowish-white and non-crystalline, but is nged washing, or more quickly by boiling in the mother-liquor, into

ing chlorine through a hot solution of potassic trimolybdate, and g small quantities of manganous sulphate, as long as the solution is d darker in colour. The filtered liquid yields the double salt, after ntration, in shining orange-coloured rhombohedrons, having the angle al edges = 107° 45'. It dissolves in 384·3 pts. water at 17°, more water, by which however it is partially decomposed. It gives off 9 at 2 at. more at 160°, acquiring at the same time a darker colour; melts perature, and solidifies on cooling into a brownish-red crystalline mass. silver, it forms a precipitate containing molybdic acid, manganic oxide, , which decomposes during washing. (Struve.)

s of Silver.—*α. Neutral argentic molybdate*, Ag^2MoO^4, is obtained by e neutral potassium-salt with nitrate of silver as a yellowish-white, floc- te, which darkens on exposure to light, dissolves sparingly in water, nitric acid.—*β.* Trimolybdate of potassium forms with nitrate of silver te flocculent precipitate, of somewhat variable composition, but agreeing rmula $2Ag^2MoO^4.3MoO^3$. (Svanberg and Struve.)

olybdate, $Ag^4O.2MoO^3 = Ag^4MoO^7$, is produced by the action of hydro- nary temperatures on the neutral argentic salt; or better, by passing hrough a tube having a narrow aperture, into a saturated solution of t in moderately strong aqueous ammonia; the reduction then also takes y temperatures, but much more quickly at 90° (at higher temperatures ver may be reduced to the metallic state). By the first method it is amorphous mass; by the second, as a black, shining, crystalline powder, gular octahedrons. It is dissolved by nitric acid, with evolution of d decomposed by potash (not by dilute ammonia) with separation of oxide. (Wöhler, Ann. Ch. Pharm. cxiv. 119.)

s of Sodium.—The *neutral* or *disodic molybdate*, $Na^2MoO^4.H^2O$ ed the *monomolybdate*), is obtained by fusing molybdic anhydride with uantity of crystallised carbonate of sodium. It is easily soluble in water, in small octahedrons, which melt and give off their water at a moderate *ydric* molybdate, $NaHMoO^4$ (or *dimolybdate*, $Na^2O.2MoO^3.H^2O$), ob- ilar manner, crystallises in needles, and dissolves sparingly in cold, ing water. The *disodio-tetrahydric molybdate*, $Na^2H^4Mo^5O^{17}.5H^2O$ (or $Na^2O.3MoO^3.7H^2O$), is obtained, by adding nitric acid to a solution of n carbonate of sodium, as a bulky white precipitate, more soluble than ing potassium-salt. Nitric acid, added in excess to a solution of odium, throws down nothing but molybdic anhydride. (Svanberg and

chloride of phosphorus. In contact with *zinc* it eliminates hydrogen from *hydrochloric acid*, and on addition of a *copper-salt*, reduces copper on its surface. (Wöhler and Rautenberg, Ann. Ch. Pharm. cix. 374.)

MOLYBDENUM, SULPHIDES OF. Molybdenum unites with sulphur in three proportions, forming the compounds MoS^2, MoS^3, and MoS^4. The last two are sulphur-acids. Our knowledge of these sulphides and their salts is almost wholly due to the researches of Berzelius.

Disulphide or Molybdic Sulphide. MoS^2.—This compound occurs native as *Molybdenite* (*Molybdänglanz*, *Wasserblei*), generally in crystallo-laminar masses, more rarely in tabular crystals, ∞P . oP, belonging to the hexagonal system, cleavable parallel to oP. Hardness = 1 to 1·5; easily impressed by the nail. Specific gravity = 4·44 to 4·8. The mineral has a strong metallic lustre and pure lead-grey colour; streak similar, but slightly inclined to green; it forms a grey trace on paper, and a greenish trace on porcelain. It is opaque, sectile, and almost malleable; laminæ highly flexible and elastic.

Molybdenite is of frequent occurrence in primitive rocks, being sometimes found in metalliferous veins, especially of magnetic iron ore and tin ores. It is found in Cornwall, at Caldbeck Fell in Cumberland, in Saxony, Bohemia, Sweden, Norway, and Greenland, and at numerous localities in the United States. It occurs nearly pure, but according to Svanberg and Struve, generally contains a small quantity of phosphoric acid (or phosphorus), a fact which must be borne in mind when the mineral is used for the preparation of molybdate of ammonium.

Disulphide of molybdenum is produced artificially by heating either of the higher sulphides, also by igniting the trioxide with sulphur. The artificial sulphide is a black shining powder.

The disulphide heated in closed vessels, sustains a high temperature without fusing or undergoing any change, and according to H. Rose, is not decomposed by ignition in dry hydrogen gas. When heated in the air, it is converted into molybdic anhydride, with evolution of sulphurous anhydride. Before the blowpipe on *charcoal* it gives off sulphurous anhydride, covering the charcoal with a yellowish-white incrustation; but it burns with great difficulty, and the combustion is but imperfect. On *platinum wire* it colours the outer blowpipe flame green. It colours a bead of *borax* mixed with *nitre*, dark brown in the inner flame, and light brown in the outer.

It decomposes *vapour of water* at a red heat slightly, but at a higher temperature with greater facility. It detonates with *nitre*, forming a molybdate of potassium; dissolves readily in warm *nitromuriatic acid*, producing molybdic and sulphuric acids, is easily oxidised by *nitric acid*; dissolves in boiling oil of vitriol with evolution of anhydride, and forms a blue solution.

Trisulphide. *Sulphomolybdic acid.* MoS^3.—This compound, the analogue of the trioxide, is formed by decomposing that compound with sulphydric acid, viz. (1) by passing the gas into a concentrated solution of an alkaline molybdate and precipitating with an acid; or (2) by adding sulphide of ammonium to the solution and then hydrochloric acid, both in excess. The whole of the molybdenum is then precipitated as trisulphide, which settles down quickly, and must be rapidly washed on a filter with water containing sulphydric and hydrochloric acids, to prevent oxidation. As thus obtained it is a black-brown powder which makes a dark brown streak on porcelain. When heated it gives off sulphur, and is converted into the disulphide. It dissolves, but not readily, in caustic alkalis, more easily at the boiling heat, undergoing partial decomposition at the same time. It is most easily dissolved by *alkaline monosulphides* and *sulphydrates*, forming sulphur-salts called sulphomolybdates; the alkaline disulphides do not dissolve it.

The sulphomolybdates are the analogues of the molybdates, most of them being constituted according to the formula $R^2S.MoS^3$ or R^2MoS^4. There are also a few containing 2 or 3 at. of the sulphur-acid. The sulphomolybdates of the alkali-metals, alkaline earth-metals, and magnesium, are soluble in water; the rest are insoluble. The alkali-metal salts are obtained by passing sulphydric acid gas into concentrated solutions of the corresponding molybdates; the insoluble salts by precipitating a neutral oxygen-salt of the metal with a soluble sulphomolybdate.

The aqueous solutions of neutral sulphomolybdates have a fine red colour when pure, changing to brown, however, if they contain a small quantity of iron or an excess of the sulphur acid. During evaporation, they emit a constant odour of sulphydric acid. When exposed to the air, they remain unaltered, if they contain an excess of the sulphur-acid; in the contrary case, the solutions—and likewise the dry salts—are rapidly oxidised, the sulphide of the alkali-metal being converted into hyposulphite, while the trisulphide of molybdenum is partly precipitated as such, partly converted into trioxide and blue oxide of molybdenum. The sulphomolybdates are decomposed by acids,

drying. The salt heated in an atmosphere of hydrogen is only partially decomposed into disulphide of potassium and molybdous sulphide.—*β.* Another salt containing a larger proportion of molybdic trisulphide, is precipitated as a brown-yellow powder, when the solution of the neutral salt is mixed with a quantity of acetic acid sufficient to give it an acid reaction. It is black after drying, and dissolves easily in boiling, slowly in cold water, forming a yellow solution. A solution of the neutral salt, mixed with a small quantity of any other acid, becomes darker, in consequence of the formation of this compound, but does not yield a precipitate.

A compound of *sulphomolybdate* and *nitrate of potassium* is obtained when a solution of equal parts of the two salts is left to evaporate. It then separates in green metallic-shining scales, very much like sulphomolybdate of potassium, which burn away like gunpowder when heated.

The *silver-salt* resembles the lead-salt in colour and streak.

Sodium-salts.—The *neutral salt* forms small dark red granular crystals, much more soluble in alcohol than the potassium-salt. It is almost completely reduced by ignition in hydrogen gas. There is also an *acid* sulphomolybdate of sodium, much less soluble than the neutral salt, and resembling the corresponding potassium-salt in all its properties.

The *strontium-salts* resemble the barium-salts.

The *uranium-* and *zinc-*salts are dark brown precipitates; the *stannous* salt is a black precipitate; the *stannic* salt, a translucent brown precipitate becoming grey-brown when dry.

Tetrasulphide of Molybdenum. *Persulphomolybdic acid*, MoS^4.—This sulphide is thrown down by hydrochloric acid from the solutions of alkaline persulphomolybdates, as a flocculent translucent precipitate of a fine dark red colour, shrinking together when dry, into a coarse-grained mass, possessing a dark green metallic lustre, and yielding a dark red powder when triturated with water. It is insoluble in water and in acids. When heated in a retort, it gives off water and a small quantity of sulphurous anhydride, then a large quantity of sulphur, and leaves disulphide of molybdenum.

Persulphomolybdates. Tetrasulphide of molybdenum unites with basic metallic sulphides, forming salts represented by the formula $R^2S.MoS^4 = R^2MoS^5$. Most of them are dark red and retain their colour unaltered when dry. The persulphomolybdates of the alkali-metals are soluble in water, and their solutions yield with acids a precipitate of molybdic tetrasulphide.

The *ammonium-salt* is obtained by drenching moist molybdic tetrasulphide with sulphydrate of ammonium, to which a little caustic ammonia may be advantageously added. A yellow powder is then formed, which becomes dark red when dry, is insoluble in alkaline liquids, sparingly soluble in cold, easily in hot water.

Barium-salt.—Yellow or red precipitate, insoluble in water, and not decomposed by dilute hydrochloric acid. The *calcium-salt* is precipitated after some time by alcohol from a mixture of the potassium-salt with chloride of calcium, as a cinnabar-coloured powder slightly soluble in water.

The *copper-salt* is a precipitate dark coloured at first, but becoming red inclining to brown after it is collected. The *gold-salt* (auric) is a brown precipitate which turns yellow and decomposes in drying, and when heated in contact with the air, burns, gives off sulphurous anhydride, assumes a golden-yellow colour, and when very strongly heated, yields a sublimate of molybdic trioxide.

Iron-salt.—Red precipitate formed on adding the potassium-salt to an excess of a ferrous salt.

The *lithium-salt* resembles the potassium-salt. The *magnesium-salt* is an insoluble red precipitate.—The *mercurous salt* is a dark almost brown precipitate.

Potassium-salts.—When sulphomolybdate of potassium is boiled with molybdic trisulphide (such a mixture is obtained by decomposing an acid molybdate of potassium with sulphydric acid), the boiling being continued for several hours in a retort, a large quantity of sulphydric acid is given off with the watery vapours, and a copious precipitate is formed. On collecting the precipitate after cooling on a filter and washing till the wash-water gives a dark red flocculent precipitate with hydrochloric acid, a residue is obtained from which water extracts persulphomolybdate of potassium, leaving disulphide of molybdenum behind. The resulting solution is red, and generally yields the salt on evaporation in the form of a red mass, having the consistence of an extract. On one occasion, however, Berzelius observed the salt to separate from the boiled mixture on cooling, in small ruby-coloured crystalline granules which could be separated from the rest of the precipitate by levigation. They appeared under the microscope as transversely striated rectangular scales; were

IC ACID. $C^{18}H^{28}O^2$.—An oily acid, homologous with oleic acid, ther with stearic, palmitic and benic acids, by the saponification of oil of *aptera*). It is colourless or faintly yellow, has a density of 0·908, a which irritates the throat, and a faint odour. It reddens litmus paper; in common alcohol, even in the cold; solidifies at the freezing point of mposed by heating with sulphuric acid. Walter found in it 75·0 per nd 11·7 hydrogen, the above formula requiring 74·9 C, 11·8 H, and *hardt's Traité de Chim. org.* ii. 882.)

ANNIC ACID. *Maclurin.* $C^{13}H^{10}O^6$. (R. Wagner, J. pr. Chem. wetz and Pfaundler, *ibid.* xc. 445; Jahresb. 1863, p. 594.)—A variety which constitutes the chief colouring matter of old fustic (*Morus tinctoria*, Hlasiwetz and Pfaundler, *Maclura tinctoria*). It forms a large portion found in the interior of faggots of that wood, and may be obtained by deposits with boiling water and leaving the extract to cool. The acid is in the form of powder and may be purified by crystallising it several e water, and dissolving the crystalline deposit in water slightly acidulated ric acid, to separate a resinous substance, and filtering the solution when turbid. (Wagner.)

oncentrated aqueous decoction of fustic left to itself for some days yields rystalline deposit, which when pressed and twice boiled with water e consisting of crude moric acid and morate of calcium, and a solution of id, which deposits a portion of the acid on evaporation, the rest on addi- hloric acid. It may be freed from resinous impurities, first by crystal- water acidulated with hydrochloric acid, and finally by adding to the all quantity of acetate of lead, and precipitating with sulphydric acid in e acetic acid. (Hlasiwetz and Pfaundler.)

acid is deposited from its solution as a light yellow crystalline powder, icroscopic prisms. It dissolves in 64 pts. of cold, and 2·14 pts. of boiling ion having a slight acid reaction, and sweetish astringent taste; easily also *d-spirit, and ether;* but is insoluble in oil of turpentine and in fixed ereal solution is greenish by reflected and brown by transmitted light.

ition of morintannic acid is shown by the following analyses and

Morphine.—Morphine dissolves easily even in dilute acids, forming
salts. It decomposes certain salts of lead, iron, copper, and mercury,
their acids. Most morphine-salts are crystallisable, inodorous, bitter,
us; they are soluble in water and in common alcohol, insoluble in ether,
alcohol. The solutions exhibit the reactions above described for
ording to Lassaigne and Feneulle, they deposit in the circuit of the
needles of morphine at the negative, and the acid at the positive pole.
olutions mixed with *ammonia*, *potash*, *soda*, *baryta*, *lime*, or *magnesia*
e as a crystalline powder soluble in excess of the precipitant, except
magnesia, difficultly soluble in excess of ammonia. According to
Pharm. [3] xiii. 143), the precipitate formed by ammonia is composed
hombohedral crystals. Morphine-salts are precipitated by the *neutral*
e alkali-metals, and the precipitate is not soluble in excess. The *acid*
e alkali-metals precipitate only a portion of the morphine from neutral
and do not form any precipitate in cold acid solutions. *Tartaric acid*
ecipitation of morphine by the acid carbonates of the alkali-metals.

rates.—Iodomercurate of potassium throws down from aqueous sulphate te of morphine, a pulverulent precipitate, which soon becomes gelatinous, e in hydrochloric acid (v. Planta, Delffs). When morphine, mercuric odide of potassium are brought together in aqueous solution, a double ^{3}.HgI^{2} [or $C^{17}NH^{19}O^{3}.HI.Hg^{7}I^{2}$?] is precipitated, sparingly soluble in luble in alcohol. It is crystallisable, free from water of crystallisation, ed by dilute acids, even on boiling, or on addition of iodide of potas- osed by caustic alkalis. (Groves, Chem. Soc. J. xi. 97.)

Morphine is a transparent gum exhibiting traces of crystallisation.

of Morphine is uncrystallisable, very soluble in water and in alcohol; salts. This salt is contained in aqueous extract of opium.

$C^{17}H^{19}NO^{3}.C^{4}H^{2}O^{4}$.—The solution of morphine in hot concentrated tic acid soon deposits white, microscopic, needle-shaped crystals, which cent. of their weight at 110°. They are rather more soluble in cold ter, freely in aqueous ammonia and potash, not in alcohol or in ether Ann. Ch. Pharm. lxxxi. 171). A *dibasic mellitate* appears to be formed, orphous brittle mass, when cold aqueous mellitic acid is saturated with the solution is evaporated. (Karmrodt.)

Morphine forms stellate rays soluble in 1½ pt. water.

Recently precipitated pectic acid dissolves morphine, even in the cold, k gum which, after dilution with water, is thickened again by acids.)

s.—Two phosphates of morphine appear to exist, the neutral salt crystal- , the acid salt in tufts. Phosphate of sodium added to solutions of mor- ms a crystalline precipitate very soluble in hydrochloric acid.

Picric acid forms with morphine-salts a sulphur-yellow pulverulent pre anta); no precipitate with the acetate. (Merck.)

ate.—Fissured gum, soluble in water and in alcohol. (Arppe.)

ate.—Hyacinth-red; soluble, with reddish colour, in water and in ler.)

.—The *neutral salt* $(C^{17}H^{19}NO^{3})^{2}.H^{2}SO^{4}.10H^{2}O$, crystallises in tufts of ms, very soluble in water and having a silky lustre. They give off 11·87 0 at.) water at 130°. There appears also to exist an *acid* sulphate of ch is obtained by supersaturating the preceding salt with sulphuric acid, dryness, and removing the excess of acid with ether.

hine is dissolved in dilute sulphuric acid, the solution evaporated till it mpose, and cold water then poured into it, a substance called sulpho- precipitated, having a constitution similar to that of an amide—that is be regarded as produced from sulphate of morphine by elimination of

$$\underset{\text{Sulphate of morphine.}}{(C^{17}H^{19}NO^{3})^{2}H^{2}SO^{4}} - 2H^{2}O = \underset{\text{Sulphomorphide.}}{C^{34}H^{36}N^{2}O^{6}S}.$$

hide recently prepared is white and amorphous, but soon turns green tubes. It dissolves in dilute acid and alkaline liquids. Strong acids compose it, forming a brown substance.

anate, $C^{17}H^{19}NO^{3}.CyHS$.—An alcoholic solution of morphine saturated ly concentrated sulphocyanic acid yields small, shining, limpid needles 100°.

tions of morphine are not precipitated by sulphocyanate of potassium.

. α. Neutral, $C^{17}H^{19}NO^{3}.C^{4}H^{6}O^{6}.3H^{2}O$.—When a solution of cream of alised with morphine, cream of tartar crystallises out first, then nodules e-salt, which must be removed in time, so as to keep them separate from rtrate of potassium which afterwards crystallises out. The salt may d by slow evaporation of an aqueous solution of tartaric acid neutralised . It forms nodular groups of crystals consisting of closely aggregated esces on the surface at 20°; loses on the average 6·54 per cent. water at 6·8 per cent.), no more at 145°. Exhibits crystal-electricity (ii. 411) o 130° or 140°, and retains it for an hour after cooling. Soluble in alcohol. ned aqueous solution is not precipitated by caustic alkalis, alkaline carbo- e of calcium, or ammonio-chloride of calcium. (Arppe, J. pr. Chem.

t, $C^{17}H^{19}NO^{3}.C^{4}H^{6}O^{6}.\frac{1}{2}H^{2}O$.—Obtained by mixing the solution of the th as much tartaric acid as it already contains. Crystallises by spon- ration in tufts of long rectangular flattened prisms. The air-dried salt per cent. (½ at.) water at 140°.

ERS. *Amyl-mucic acid*, $C^6H^9(C^5H^{11})O^8$, is produced by the action on a mixture of amylic alcohol and mucic acid. It is crystallisable, ng water and in alcohol.

Ethyl. The *neutral* compound, $C^{16}H^{18}O^8 = C^6H^9(C^2H^5)^2O^8$, commonly *er*, is prepared by gently heating 1 pt. of mucic acid with 4 pts. of ll it turns black, then leaving it to cool, and adding 4 pts. of alcohol of 0·814. The mixture left to itself for 24 hours solidifies in a mass, shaken up with alcohol, thrown on a filter, washed with alcohol, and ated crystallisation from boiling alcohol.

yl crystallises in transparent four-sided prisms, terminated by a single ce. It is insipid at first, but leaves a bitter aftertaste. It melts at les in a crystalline mass at 135°. At a higher temperature it is re-ol, water, carbonic anhydride, acetic acid, carburetted hydrogen, pyro-charcoal. It is insoluble in ether, very soluble in boiling alcohol, very alcohol; very soluble also in boiling water, which deposits it in well-on cooling. The alkaline hydrates decompose it like other ethers: ts it into mucamide.

id or *Mucovinic acid*, $C^8H^{14}O^8 = C^6H^9(C^2H^5)O^8$. In the preparation of mucate, it sometimes happens that an aqueous solution of that com-ure, gives off all at once a very decided alcoholic odour, and yields by ubstance totally different in appearance from the neutral ether. It is ment with alcohol, which removes the neutral ether, and the residue is or three times from water. The product is pure when its solution is ed turbid by ammonia.

id is white, of asbestos-like aspect, the form of its crystals being that with rhombic base. It is moderately soluble in water, very slightly as a pure acid taste, and melts at 190°, with decomposition. The umes a vitreous aspect on cooling, but after a considerable time it n becomes opaque.

f ammonium, $C^6H^{12}(NH^4)O^8$, is very soluble, tasteless, and has a slight ts solution precipitates the salts of *lead*, *silver*, *copper*, *barium*, and slightly those of *calcium*, and forms no precipitate with salts of *zinc*, All the precipitates are soluble in acetic acid.

on of ethylmucic acid is boiled with oxide of silver, carbonic anhydride tion of the oxide is reduced, and a silver-compound is formed, which lightly heated.

Methyl, $C^8H^{14}O^8 = C^6H^9(CH^3)^2O^8$, is prepared like mucate of ethyl, from water or alcohol in laminæ, or in flattened six-sided prisms, olatile, and tasteless. It is very soluble in boiling water, very little in It decomposes at 163° without melting, and then changes to a black ells up, and gives off gases containing carbon.

AM. From experiments on the growth of these fungi (*Ascophora* in (Compt. rend. lvii. 771) concludes that they require for their normal elements of phosphate and sulphate of ammonium and of the carbo-m, magnesium and manganese, but that these elements are not all of em. If 20 grms. of the plant are produced in a given time in a liquid e substances above mentioned, then in the same time there will be bsence of manganese, 5 grms.; of sulphur, 2 grms.; of potassium and 1 grm.; and in the absence of phosphorus, only half a gramme of the ents in which these fungi were developed in a confined volume of air, nitrogen of the air was not essential to their growth. Similar results, the mineral constituents, have been obtained with plants of higher lle (Compt. rend. lvii. 270).

LIER, or *Galvanometer* (see ELECTRICITY, ii. 443).

T. *Rubia Munjista.*—This plant, also called *East Indian madder*, is ltivated in India, its root being used as a dyestuff for producing colours se obtained from ordinary madder. The colouring matters contained in ver, by no means identical with those of common madder; in fact, as shown that it contains no alizarin, but that its colouring matter is a rpurin and an orange-dye, called munjistin (see the next article). The it produces are brighter than those of ordinary madder, but not so

ial power of munjeet was first examined by Runge in 1835, who reported ned about twice as much available colouring matter as ordinary madder; t experiments, both by German and by English dyers, have shown that as incorrect, and that the colouring power of munjeet is actually much of ordinary madder.

amount of colouring matter in munjeet is indeed very nearly the same madder. Stenhouse finds that the garancin from munjeet has about orial power of that made from the best madder, viz. Naples roots; these, only about 30 to 33 per cent. of garancin, whereas munjeet, according to nts of Mr. Higgin of Manchester, yields from 52 to 55 per cent.

rity of munjeet as a dyestuff results from its containing only the com-ble colouring matters purpurin and munjistin, only a small part of the available, while its presence in large quantity appears to be positively much so, indeed, that munjeet-garancin, freed by boiling water from the of the munjistin which it contains, yields much richer shades with ants than before. (Stenhouse, Proc. Roy. Soc. xiii. 148.)

TIN. $C^9H^6O^3$. (Stenhouse, Proc. Roy. Soc. xii. 633; xiii. 86, 145.)—olouring matter contained, together with purpurin, in munjeet or East r. It is nearly related in composition to purpurin, $C^9H^6O^3$, and alizarin, ring from the former by 1 at. and from the latter by 2 at. carbon. It njeet in considerable quantity, and may be extracted by the following

l of munjeet in fine powder is boiled for four or five hours with 2 pounds f aluminium and about 16 pounds of water, the operation being repeated imes; the red liquor thus obtained is strained through cloth filters while ; and the clear filtrate is saturated with hydrochloric acid, whereby a ecipitate is soon produced, which goes on increasing in quantity for hours if the liquid is left at rest. This precipitate is collected on cloth shed with cold water till the greater part of the acid is removed; then sed, and digested in a percolator with boiling sulphide of carbon, which rystallisable colouring principles of the munjeet, and leaves a considerable rk-coloured resinous matter. The excess of sulphide of carbon having by distillation, the bright-red extract, consisting chiefly of a mixture of l purpurin, is repeatedly treated with moderate quantities of boiling ered, the clear yellow filtrate consisting of a solution of munjistin, while e purpurin remains on the filter. The solution acidulated with hydro-lphuric acid deposits the munjistin in large yellow flocks, which are ed on a filter with cold water, then dried by pressure, and dissolved in of wine, slightly acidulated with hydrochloric acid, to remove any adher-As the munjistin does not subside from cold alcoholic solutions, even e largely diluted with water, about three-fourths of the spirit must be fter which the munjistin is deposited in large yellow scales. By two or sations from spirit, in this manner, it may be rendered perfectly pure.

nay also be extracted directly from munjeet by boiling with water, acidu-rk brownish-red filtrate with hydrochloric acid, and treating the precipi-; but the process above described yields a better product. The colouring

MUREXAN. *Dialurimide* (Laurent).—Disc
Phys. xi. 48), who called it *Purpuric acid:* furth
Ann. xix. 12), and by Liebig and Wöhler (A
formed by the decomposition of murexide by the
gen, or potash. It is obtained by adding sulphu

Digitized by Google

urexide in water or potash: the crystalline precipitate is purified by cold sulphuric acid, and precipitating by water; or by dissolving it precipitating it by an acid. It is thus obtained as a heavy white ous like uramil, infusible, tasteless, and does not redden litmus. It air containing ammonia. It is almost insoluble in cold *water*, re- han 10,000 pts.: insoluble in alcohol, ether, dilute sulphuric, hydro- phoric acid, or in aqueous, acetic, tartaric, or citric acid. It is soluble *sulphuric* acid, and reprecipitated by water; also in aqueous *alkalis*, alising them, forming solutions which are colourless when air is ex-

decomposed by *dry distillation*, yielding cyanic acid and other products. l and decomposed by *chlorine-water*, without yielding cyanic acid. with strong *nitric acid* it is dissolved with effervescence, giving off rbonic anhydrides, and yielding on evaporation crystals of oxalate of dweiss). When heated with *sulphuric acid*, it evolves carbonic anhy- de nitrogen, and forms a brown solution, containing ammonia, and not y water. Its colourless solution in *ammonia* turns purple when ex- r, and on evaporation yields crystals of murexide:

$$\underset{\text{Murexan.}}{C^8H^7N^5O^6} + O + NH^3 = \underset{\text{Murexide.}}{C^8H^6N^6O^6} + H^2O.$$

ution is decolorised by exposure to oxygen-gas, oxalurate of ammonium

n circumstances murexan appears to combine with acids. It dissolves *nitric acid* without effervescence, and yields on evaporation small which appear to be nitrate of murexan. When dissolved in *oxalic acid* tle nitric acid, or when heated with strong nitric acid, it yields crystals , which, according to Kodweiss, are oxalate of murexan.

tion of murexan is very variously stated. The analyses of Liebig and of Kodweiss, yield very conflicting results: the former agrees toler- rmula $C^8H^7N^5O^6$, which is accordingly adopted by Liebig and Wöhler *him. org.* i. 1517) considers murexan as identical with dialuramide, view which is advocated by Beilstein (Ann. Ch. Pharm. cvii. 191), hose analyses murexan contains 29·54 per cent. nitrogen, which agrees 29·38, the calculated percentage in $C^8H^5N^5O^5$. Gmelin adopts the $^6O^6$, which gives percentages intermediate between the analyses, and mplest equations. Laurent (Compt. rend. xxxv. 629) adopts the same egards the compound as dialurimide—$N.C^8H^6N^4O^4.H$.

Digitized by Google

When a moderately concentrated aqueous solution of myronate of potassium is mixed with *nitrate of silver*, nitric acid is set free, and a white curdy precipitate is formed, containing, when dried over oil of vitriol, the elements of sulphocyanate of allyl and sulphate of silver ($C^6H^5Ag^2NS^2O^4 = C^6H^5NS.Ag^2SO^4$). Its formation is represented by the equation,

$$C^{10}H^{18}KNS^2O^{10} + 2AgNO^3 = C^6H^5Ag^2NS^2O^4 + C^6H^{12}O^6 + KNO^3 + HNO^3.$$

This silver-compound, heated either alone or with water, is resolved into sulphocyanate of allyl, sulphate of silver and sulphide of silver; it is also decomposed, with evolution of mustard-oil, by *chloride* or *sulphide of barium*, or by *zinc*. When it is treated with *hydrochloric acid*, the liquid filtered from the chloride of silver contains half the sulphur in the form of sulphuric acid, but no sulphydric acid or sulphocyanate of allyl is produced. The silver-compound, suspended in a large quantity of water, is decomposed by *sulphydric acid*, with formation of a precipitate of sulphur and sulphide of silver; and the strongly acid filtrate, which contains half the original quantity of sulphur in the form of sulphuric acid, yields by repeated distillation an oily layer, consisting of cyanide of allyl, $C^3H^5.CN$:

$$C^6H^5Ag^2NS^2O^4 + H^2S = C^4H^5N + Ag^2S + S + H^2SO^4.$$

The cyanide of allyl thus produced differs considerably in its properties from that which Lieke obtained by the action of cyanide of silver on iodide of allyl (ii. 203). It is a colourless neutral oil of agreeably alliaceous odour and burning aromatic taste. Specific gravity = 0·8389 at 12·8°. Vapour-density = 2·32 (calc. 2·31); boiling point 116° (corrected 118·3°). Heated with strong potash-ley in a sealed tube, it is resolved into ammonia and crotonic acid, $C^4H^6O^2$. (Will and Körner.)

MYROSIN. An emulsion-like substance, of the albuminous or protein class, contained in the seeds of black and white mustard, and possessing the property of decomposing the myronate of potassium contained in the former, with production of sulphocyanate of allyl or volatile oil of mustard. It is likewise contained in the seeds of other cruciferous plants, viz. *Raphanus sativus*, *Brassica Napus*, *Br. oleracea* and *Br. campestris*, *Alliaria officinalis*, *Cheiranthus Cheiri*, *Draba verna*, *Cardamine pratensis*, *C. amara* and *Thlaspi arvense*. (Lepage.)

To prepare it, pulverised white mustard is exhausted with cold water; the filtrate evaporated to a syrup at a temperature below 40°; the syrup precipitated by a moderate quantity of alcohol; the precipitate dissolved in water after the alcohol has been poured off; and the solution evaporated to dryness at a temperature below 40°.

Myrosin, as thus obtained, resembles other protein-compounds. When incinerated, it leaves sulphate of calcium.

In the state of aqueous solution, it is coagulated by heat and also by alcohol, and loses its power of eliminating oil of mustard from myronic acid, but recovers this power after immersion in water for twenty-four to thirty-six hours. It does not eliminate hydrocyanic acid from amygdalin.

The aqueous solution of myrosin is transparent, colourless, and gummy, and froths when agitated. (Bussy, J. Pharm. xxvi. 44; Winckler, Jahrb. pr. Pharm. iii. 93.)

MYROXOCARPIN. (Stenhouse, Ann. Ch. Pharm. lxxviii. 306.)—A crystallisable substance extracted from white Peru balsam (i. 496). On digesting this balsam with alcohol of ordinary strength, a great part dissolves, and the solution gradually deposits large crystals of myroxocarpin mixed with resin; they may be purified by recrystallisation with aid of animal charcoal.

Myroxocarpin crystallises in large thin, colourless, shining prisms, often an inch long. According to a determination by Miller, they belong to the trimetric system, the ratio of the principal axis, macrodiagonal and brachydiagonal, for the primary octahedron P, being as 1 : 0·9363 : 0·7553. Observed combination $\infty P . oP . \infty\breve{P}\infty . \breve{P}\infty . 2\breve{P}\infty . \bar{P}\infty . 2\bar{P}\infty$. Angle $\infty P : \infty P = 102° 12'$; $\bar{P}\infty : oP = 127° 4'$; $2\bar{P}\infty : oP = 110° 41'$; $\breve{P}\infty : oP = 133° 7'$; $2\breve{P}\infty : oP = 115° 5'$. The crystals are hard and brittle, insoluble in water, very soluble in hot alcohol and ether, tasteless, and neutral to test-papers. They give by analysis 77·18 per cent. carbon, and 9·5 hydrogen, which may be represented by the formula $C^{18}H^{35}O^8$, or $C^{18}H^{70}O^8$.

Myroxocarpin melts at 115° to a transparent glass, which does not crystallise on cooling, but if redissolved in boiling alcohol, is again deposited in the crystalline form. Heated considerably above its melting point, it yields a sublimate, together with much acetic acid, and an uncrystallisable resin.

It does not unite with *acids*, or with *alkalis*, and is not attacked by boiling *potash-ley*.

Hot *nitric acid* slowly converts it into oxalic acid and an uncrystallisable resin. *Chlorine*, with aid of heat, likewise converts it into an amorphous resin.

Lead:	
Metallurgical Treatment of Lead ores	481
I. Reduction of Lead ores	—
1. Reduction of Sulphur ores in Reverberatory Furnaces	482
a. Method by double decomposition	—
English Process	—
Carinthia Process	485
French Process	486
Analysis of Lead-slags from Reverberatory Furnaces	487
Action of the Gangue	—
b. Process by Affinity	488
The reduction of Oxygen ores of Lead	489
Spanish Air Furnace or *Horno de Gran Tiro*	—
2. The reduction of Lead-ores in Blast Furnaces	491
a. The Cupola or Blast Furnace	—
Silesian Furnace	—
Hartz Furnace	—
Analyses of Matts	492
Analyses of Lead-slags from Blast Furnaces	493
Spanish Economic Furnace	495
b. The Ore Hearth	497
The Backwoods Hearth	—
The American Hearth	—
The Scotch Hearth	—
Chemical reactions in the Blast Furnace	501
II. The Refining of the Lead	504
1. Desilverisation: Pattinson's Process	—
Stagg's Apparatus—Worsley's Apparatus	507
Parkes' Process	—
Separation of Copper in crystallisation	508
2. Cupellation or Refining of rich Lead	—
The English system	—
Chambers's Steam Blast	510
Johnson's Process	511
The German System	512
Separation of Lead from Bismuth	513
Manufacture of Litharge	514
3. Reduction of the Pot-dross and Litharge	515
III. Softening of Hard Lead	516
Calcination of the Lead	—
Pontifex and Glassford's Process	518
Reduction of the Dross	519
Separation of the Antimony	—
Cost of treating Spanish Hard Lead	520
IV. Smelting of the Slags and other products:	
1. The English Slag Hearth	—
2. The Clausthal Blast Furnace	521
V. Condensation of the Lead Fume	528
Stokoe's Condenser	—
Stagg's Condenser	524
Analyses of Lead-Fumes	526
